35 **ABSTRACT**

36

37 Impacts of climate change require that society urgently develops ways to reduce amounts of  
38 carbon in the atmosphere. Tropical forests present an important opportunity, as they take up  
39 and store large amounts of carbon. It is often suggested that forests with high biodiversity  
40 have large stocks and high rates of carbon uptake. Evidence is, however, scattered across  
41 geographic areas and scales, and it remains unclear whether biodiversity is just a co-benefit or  
42 also a requirement for the maintenance of carbon stocks and uptake. Here, we perform a  
43 quantitative review of empirical studies that analysed the relationships between plant  
44 biodiversity attributes and carbon stocks and carbon uptake in tropical forests. Our results  
45 show that biodiversity attributes related to species, traits or structure significantly affect  
46 carbon stocks or uptake in 64% of the evaluated relationships. Average vegetation attributes  
47 (community-mean traits and structural attributes) are more important for carbon stocks,  
48 whereas variability in vegetation attributes (i.e. taxonomic diversity) is important for both  
49 carbon stocks and uptake. Thus, different attributes of biodiversity have complementary  
50 effects on carbon stocks and uptake. These biodiversity effects tend to be more often  
51 significant in mature forests at broad spatial scales than in disturbed forests at local spatial  
52 scales. Biodiversity effects are also more often significant when confounding variables are not  
53 included in the analyses, highlighting the importance of performing a comprehensive analysis,  
54 which adequately accounts for environmental drivers. In summary, biodiversity is not only a  
55 co-benefit, but also a requirement for short- and long-term maintenance of carbon stocks and  
56 enhancement of uptake. Climate change policies should therefore include the maintenance of  
57 multiple attributes of biodiversity as an essential requirement to achieve long-term climate  
58 change mitigation goals.

## 64 INTRODUCTION

65

66 The global increase in emissions of greenhouse gases such as CO<sub>2</sub> has led to rapid changes in  
67 climate, occurring at unprecedented rates compared to the last 1300 years (IPCC 2014).

68 Simultaneously, anthropogenic disturbances have resulted in a loss of species diversity, with  
69 the current rate of extinctions being at least 1000 times higher than natural extinction rates

70 (De Vos *et al.* 2015). These changes have raised international concerns and stimulated

71 initiatives such as the Kyoto Protocol to reduce emissions and combat climate change, and the

72 Convention on Biological Diversity to conserve and sustainably use biodiversity. During the

73 climate change conference of the United Nations Framework Convention on Climate Change

74 (UNFCCC) in December 2015 in Paris, 196 countries agreed to keep global warming below 2

75 °C (United Nations 2015). To achieve this goal, countries need to implement effective

76 mitigation strategies.

77 Tropical forests are particularly important for climate change mitigation and

78 biodiversity conservation initiatives. They are crucial ecosystems of both carbon stocks and

79 biodiversity; they host around 47,000 tree species (Slik *et al.* 2015), store 25% of global

80 terrestrial carbon in plant biomass (Bonan 2008) and account for 34% of gross primary

81 productivity (Beer *et al.* 2010). The Reduced Emissions from Deforestation and forest

82 Degradation (REDD+) policy, UNFCCC's most relevant policy for carbon mitigation in the

83 tropics, recognizes the importance of conserving biodiversity as a co-benefit of conserving

84 carbon to avoid unintended negative effects for biodiversity (Phelps, Webb, *et al.* 2012). The

85 question remains, however, whether biodiversity also directly contributes to, and is thus a

86 requirement for, maintaining carbon stocks and carbon uptake (hereafter termed CSU, where  
87 ‘uptake’ mostly refers to biomass growth, see Glossary; Balvanera *et al.* 2006; Díaz *et al.*  
88 2009).

89         Various ecological theories predict that biodiversity is a requirement for CSU. Here,  
90 we refer to ‘biodiversity’ as general vegetation attributes, including aspects that represent  
91 variability in vegetation attributes (e.g., species and trait diversity) as well as aspects that  
92 represent average vegetation attributes (e.g., community-mean trait values and vegetation  
93 structure, Glossary, Table 1). The niche complementarity theory (Tilman 1999) predicts that  
94 diversity in the number and functioning (i.e., trait diversity or functional diversity) of species  
95 should increase resource use efficiency and therefore lead to greater carbon uptake, and  
96 hence, greater carbon accumulation over time and larger carbon stocks per area of forest  
97 (Chisholm *et al.* 2013). Species diversity may also enhance CSU through facilitation among  
98 species (Hooper *et al.* 2005) and through reduced impact of species-specific pathogens  
99 (Schnitzer *et al.* 2011). Contrary to these diversity theories, the mass-ratio theory (Grime  
100 1998) predicts that the most dominant species and their characteristics, rather than the  
101 diversity of species, determine ecosystem processes. In addition to the effects of number and  
102 type of species, the structural attributes of the vegetation (such as tree density and plot basal  
103 area) and/or environmental conditions (such as climate and soil fertility) also strongly  
104 determine CSU (Poorter *et al.* 2015). Finally, the nature of biodiversity-CSU relationships  
105 could change across spatial and temporal scales. For example, at short temporal scales, greater  
106 redundancy among species – and hence a lower importance of species and trait diversity –  
107 may occur than at long temporal scales (Cardinale 2012).

108         Evidence for an effect of biodiversity on CSU has been provided by local-scale  
109 experiments and empirical field studies carried out mainly in temperate grasslands or other  
110 relatively simple ecosystems (Balvanera *et al.* 2006, Tilman *et al.* 2001, Fraser *et al.* 2015,

111 Paquette & Messier 2011). Furthermore, several reviews have been carried out but these are  
112 dominated by results from temperate grasslands (e.g., Hooper *et al.* 2012) or focused on  
113 forests in general and are mostly conceptual (e.g., Díaz *et al.* 2009). Yet, evidence from  
114 highly diverse and structurally complex tropical forests has only recently become available  
115 and is still fragmented (e.g., Bunker *et al.* 2005, Poorter *et al.* 2015). This evidence is  
116 therefore insufficient at present to inform on the design and implementation of policies such  
117 as REDD+.

118         Here, we perform a quantitative review on empirical studies that evaluate the  
119 relationships of tree biodiversity with carbon stocks and uptake (CSU) in tropical forests. We  
120 focus on different attributes of biodiversity (taxonomic diversity, trait diversity, community-  
121 mean traits, and structural attributes; Table 1) related to community-level vegetation  
122 attributes. These attributes describe the average as well as the variability in vegetation  
123 attributes. Furthermore, we focus on stocks and uptake separately because they may be driven  
124 by different biodiversity attributes. We evaluate how different biodiversity attributes relate to  
125 CSU, and how the relationship of biodiversity attributes with CSU is influenced by spatial  
126 scale, management intensity, and analytical approach. We then synthesize this information to  
127 evaluate under which conditions biodiversity is important for CSU and which ecological  
128 theories can explain this. Finally, we provide recommendations on the policy implications of  
129 our findings and on the next steps required to improve our understanding of biodiversity-CSU  
130 relationships in tropical forests.

131

132

## 133 **METHODS**

134

### 135 **Selection of studies**

136 We searched the literature for peer-reviewed studies as well as yet unpublished studies that  
137 were part of the ROBIN-project (Role Of Biodiversity In climate change mitigation,  
138 <http://robinproject.info/home/>) that evaluate biodiversity effects on CSU (see Appendix S1 for  
139 details on study selection). We also considered the effect of environment, if reported in the  
140 study. As our unit of replication, we used each reported relationship between a biodiversity  
141 attribute group or environmental attribute and CSU. Hence, if a study tested the effect of one  
142 biodiversity attribute on one component of CSU, then this study yielded one relationship, but  
143 if the study tested for multiple biodiversity attributes and/or multiple CSU components, then  
144 this study yielded multiple relationships. To increase the number of relationships assessed per  
145 group and better understand the role of biodiversity attributes in carbon stocks and the uptake  
146 of carbon, we grouped the different measures of CSU into ‘carbon stocks’ (including above-  
147 and belowground carbon or biomass stocks, and soil organic matter or soil carbon) and  
148 ‘carbon uptake’ (including (litter) productivity, (net) growth, and loss through tree mortality)  
149 (Appendix S2).

150

### 151 **Quantitative review of studies**

152 We found 38 empirical studies that describe 165 relationships between one or more of the  
153 four biodiversity attributes and carbon stocks (64 relationships) and/or uptake (101  
154 relationships) in tropical forests (Table 1, and see Appendix S2 and S3 for details about the  
155 studies). The studies mainly came from the Neotropics (68%), but also from Africa (8%),  
156 Asia (5%) and across multiple continents (18%). For both carbon stocks and uptake, we  
157 evaluated whether biodiversity effects were positive, negative, both positive and negative  
158 (which can occur when multiple measures of the same biodiversity attribute are tested) or  
159 neutral (i.e., not significant). For community-mean trait effects, we did not distinguish

160 between positive and negative because the relevance of the direction depends on the trait  
161 considered (i.e., they were classified as either “significant” or “neutral”).

162 In many cases, studies used multiple variables within the same biodiversity attribute  
163 group to predict CSU (for example, taxonomic richness and Shannon diversity). In these  
164 cases, we summarized the multiple variables within one biodiversity attribute group as one  
165 relationship in the following way; in case both positive and non-significant effects were  
166 found, then we gave the relation a ‘positive’. Similarly, in case both negative and non-  
167 significant effects were found, then the relation was given a ‘negative’. Finally, when it  
168 showed both positive and negative (and non-significant) relationships, it was given a ‘positive  
169 and negative’. We neglected the non-significant effects in these cases because the absolute  
170 amount of variables in each biodiversity attribute group may not be representative, as authors  
171 will pre-select some variables and/or not report variables that show non-significant effects.  
172 The relationship between a biodiversity attribute group and a CSU component was classed as  
173 non-significant when all tested effects were not significant. We evaluated the effect of  
174 biodiversity attributes on carbon stocks and uptake by calculating percentages of relationships  
175 that were significant. Note that ‘biodiversity attributes’ refer both to variability in vegetation  
176 attributes (i.e. taxonomic and trait diversity) and to average vegetation attributes (i.e.  
177 community-mean traits and structural attributes).

178

### 179 **Statistical analyses**

180 Using logistic regression models (with a significance level of 0.05, using the glm function of  
181 the stats package of the R software version 3.3.1, R Core Team 2016) we also evaluated  
182 whether the probability of a significant relationship between one of the biodiversity attributes  
183 and carbon stocks or uptake was statistically different from the probability of a non-  
184 significant relationship. For taxonomic diversity, trait diversity and structural attributes we

185 performed three different tests. First, we tested whether biodiversity attributes have, in  
186 general, a significant effect on CSU. We did so by testing whether the probability of a  
187 significant relationship, either *positive and/or negative*, was statistically different from the  
188 probability of a non-significant relationship. Second, we tested whether biodiversity attributes  
189 have in general a significant positive effect on CSU. We did so by testing whether the  
190 probability of a *positive* relationship was statistically different from the probability of no  
191 significant positive relationship (i.e., a neutral or negative relationship). Third, we tested  
192 whether biodiversity attributes have in general a significant negative effect on CSU. We did  
193 so by testing whether the probability of a significant *negative* relationship was different from  
194 no significant negative relationship (i.e., a neutral or positive relationship). The relationships  
195 that were both positive and negative (due to multiple indices of the same biodiversity attribute  
196 group) were included in test two and three. For community-mean traits and environmental  
197 conditions, we only performed the first test (i.e., all significant effects combined).

198 Per test, the relationships that were considered significant were given a '1' (i.e., all  
199 significant relationships in test 1, significantly positive ones in test two, and significantly  
200 negative ones in test three), while the relationships that were considered non-significant were  
201 given a '0'. The intercept of the logistic regression models represents the 'probability',  
202 defined as the log of the odds. The log of the odds is the log of the probability of being equal  
203 to 1 (i.e., for significant relationships) divided by the probability of being equal to 0 (i.e., for  
204 non-significant relationships). If the probability of significant and non-significant relationship  
205 is equal, then the odds is  $0.5/0.5 = 1$ , and hence the log odds is  $\log(1) = 0$ . If the intercept is  
206 significantly higher than 0 (i.e., the 2.5% confidence interval (CI) is higher than 0), then there  
207 is a significant probability of a significant relationship. If the intercept is significantly lower  
208 than 0 (i.e., the 97.5% CI is lower than 0), then there is a significant probability of a non-  
209 significant relationship.

210 To correct for possible differences in precision among studies, we added a weight  
211 factor as the square root of the total sampled area (the average plot size multiplied by the  
212 number of plots, Appendix S2). For the studies from which we could not reconstruct the plot  
213 size, we used the average plot size across the other studies. Because of the variety of analyses  
214 and effect sizes used among studies, and because often standard errors were missing, we  
215 could not perform a more formal meta-analysis. Details about the analyses are presented in  
216 Table 2.

217

218

## 219 **RESULTS & DISCUSSION**

220

221 We performed a literature review to evaluate how different biodiversity attributes relate to  
222 carbon stocks and uptake (CSU) in tropical forests. Generally, taxonomic diversity,  
223 community-mean traits and structural attributes were better predictors for CSU than trait  
224 diversity (Fig. 1, Table 2), and they were more often significantly related to carbon stocks  
225 than carbon uptake. Carbon stocks were most often predicted by community-mean traits and  
226 forest structure, and carbon uptake was most often predicted by forest structure and  
227 taxonomic diversity, although negative relationships were more common for carbon uptake  
228 than for carbon stocks.

229

### 230 **Biodiversity–CSU relationships**

231 Carbon stocks were significantly positively related to taxonomic diversity in 42% of the  
232 relationships, both positively and negatively in 21% of the relationships (which could occur  
233 when multiple indices for taxonomic diversity were tested, Fig. 1), and negatively in only 5%  
234 of the relationships, supporting diversity theories such as niche complementarity. However,

235 these results also indicate that some studies find no relationship or a negative relationship  
236 between taxonomic diversity and carbon stocks, suggesting that diversity mechanisms may  
237 not universally apply throughout tropical forests. The diversity of trait values only rarely had  
238 a positive effect (17%) or both positive and negative effects (33%) on carbon stocks. Trait  
239 diversity is a complex measure that is constructed using a variety of traits of which only a  
240 subset may be important for CSU (Butterfield & Suding 2013). Probably for this reason, a  
241 non-significant effect of trait diversity on CSU was often observed. Carbon stocks were  
242 significantly affected by community-mean trait values in 100% of the relationships (Fig. 1),  
243 providing support for Grime's mass-ratio theory (Grime 1998). These results were also  
244 confirmed by the results of the logistic regressions (Table 2); taxonomic diversity and  
245 community-mean traits had significant effects on carbon stocks.

246 In comparison to carbon stocks, carbon uptake was more often significantly and  
247 positively related to taxonomic diversity (53% for uptake vs. 41% for stocks), but less often  
248 when including the studies that find both positive and negative relationships (57% vs. 63%).  
249 Moreover, carbon uptake was less often significantly related to community-mean traits (47%  
250 for uptake vs. 100% for stocks). These results are also supported by the logistic regression  
251 models, which showed a significant positive effect of taxonomic diversity on carbon uptake  
252 (Table 2) but a non-significant effect of community-mean traits on carbon uptake (Fig. 1,  
253 Table 2). In agreement with these results, the studies that present standardized correlation or  
254 regression coefficients ( $\beta$ ) show that the effect of community-mean traits is strong for carbon  
255 stocks ( $\beta$  up to 0.6), and that the effect of species diversity can be strong for both carbon  
256 stocks and carbon uptake ( $\beta$  up to 0.3-0.4). Hence, community-mean traits are more important  
257 for carbon stocks, whereas taxonomic diversity is important for both carbon stocks and  
258 uptake.

259 Most reviewed studies support the idea that stands with high diversity have higher  
260 complementary in resource use and can therefore be more productive and store more biomass,  
261 and that stands dominated by tall and dense-wooded trees (as determined by community-mean  
262 traits) have higher carbon stocks. Studies that report significant effects of community-mean  
263 traits on carbon uptake show that, in most cases, acquisitive trait values (e.g., high specific  
264 leaf area) increase carbon uptake (e.g., Finegan *et al.* 2015). However, some studies on sites  
265 with stronger limitation of water and/or soil nutrients showed that acquisitive trait values  
266 decreased carbon uptake, possibly because such traits result in higher respiration and lower  
267 survival rates in harsh conditions, and consequently lead to lower total carbon gain (e.g.,  
268 Prado-Junior *et al.* 2016, van der Sande, *et al.* in review).

269 Structural attributes (e.g., tree density and plot basal area, Table 1) had a consistent  
270 positive effect on carbon stocks in 78% of the relationships. Structural attributes, often  
271 indicating forest density, were positively related to carbon stocks because denser forests may  
272 have more and larger stems, and since most carbon is held in stems, this directly increases  
273 carbon stocks (e.g., Poorter *et al.* 2015). Although a relationship between structural attributes  
274 and carbon stocks is expected because they are used to calculate carbon stocks, it is important  
275 to understand the relative importance of structural attributes and biodiversity in determining  
276 CSU. Contrary to the positive effect on carbon stocks, structural attributes had mixed effects  
277 on carbon uptake; they were positively related to carbon uptake in 44% of the relationships  
278 and negatively related in 33% of the relationships. Two mechanisms can possibly explain the  
279 positive and negative effects of structural attributes on carbon uptake. On the one hand, a  
280 large quantity of leafy vegetation could lead to high productivity because many leaves are  
281 available to assimilate carbon (e.g., Peh 2009). On the other hand, large plants and dense  
282 vegetation that compete for resources and space could reduce stand-level carbon uptake  
283 because less light, water and nutrients are available for growth of other individuals (e.g.,

284 Phillips *et al.* 1994). Structural attributes were significantly positively related to carbon  
285 stocks, and significantly related to carbon uptake only when combining all studies that find  
286 significant relationships, and was not significantly positively or negatively related to carbon  
287 uptake (Fig. 1, Table 2). In agreement with these results, the studies reported generally larger  
288 effect sizes of structural attributes for carbon stocks ( $\beta$  up to 0.9) than for carbon uptake ( $\beta$  up  
289 to 0.5-0.6).

290 Overall, we found that biodiversity attributes generally better predict carbon stocks  
291 than carbon uptake. Carbon stocks are most often significantly related to biodiversity  
292 attributes that relate to *average* vegetation attributes (i.e. the community-mean traits and  
293 structural attributes), whereas carbon uptake is most often significantly positively related to  
294 biodiversity attributes that relate to *variability* in vegetation attributes (i.e. taxonomic  
295 diversity). These results also agree with additional recent publications showing that  
296 community-mean traits are more important for carbon stocks than taxonomic diversity  
297 (Sullivan *et al.* 2017), and that taxonomic diversity is important for carbon uptake (Liang *et*  
298 *al.* 2016). The different results of carbon stocks versus uptake also indicate that these are not  
299 necessarily positively correlated. An increase in carbon uptake could lead to higher carbon  
300 build-up and thus higher stocks (Chisholm *et al.* 2013), but it could also be that dynamic  
301 forests with high carbon uptake have a high abundance of fast-growing species with short  
302 lifespan and high turnover, which would decrease overall carbon stocks (Keeling & Phillips  
303 2007).

304 When combining all biodiversity attributes, then biodiversity had a significant effect  
305 on carbon stocks and uptake (Table 2). This indicates that biodiversity in general is important,  
306 but that we need to understand better which biodiversity attribute matters for which ecosystem  
307 process (e.g., carbon stocks vs. uptake) and under what conditions. Across our studies,  
308 environmental variables also had a significant effect on both carbon stocks (82% of the

309 relationships, Fig. 1, Table 2) and uptake (79%). Where significant, the reviewed studies  
310 show that standardized effect size ( $\beta$ ) of environmental variables was up to 0.67, indicating  
311 that environmental conditions may be at least as important as biodiversity attributes in  
312 explaining CSU.

313         We need to be aware of a possible publication bias due to the fact that studies that find  
314 significant effects of biodiversity attributes on CSU may be more often published than studies  
315 that find a non-significant relationship. Possible publication bias could be identified by  
316 evaluating how the probability of a significant relationship depends on the sample size of the  
317 study (in our case the total sampled forest area). Without publication bias, a larger sampled  
318 area would increase the probability of finding significant relationships between biodiversity  
319 attributes and CSU. For the studies in this review, however, we found no relationship between  
320 total sampled area and the probability of significant relationships (Appendix S4), suggesting  
321 that the publications may be biased towards studies with significant relationships. To advance  
322 science, we advocate moving from a culture in which we only valorise and publish novel  
323 papers with spectacular results, to one where we valorise and publish all solid research.

324

### 325 **Causes of variation: scale, management intensity and analytical approach**

326 Effects of biodiversity on CSU can depend on factors related to spatial scale, forest  
327 management, and the analytical approach used. We therefore evaluated how the biodiversity-  
328 CSU relationship depends on these factors. We summarized this only in a descriptive way, as  
329 in most cases the sample sizes were too small (see Fig. 2) to do a formal statistical analysis.

330         *Biodiversity-CSU relationship at different spatial scales* – Ecological processes  
331 operate at different spatial scales (McGill 2010). At local spatial scales (i.e., within one plot or  
332 study site) with low variation in abiotic conditions, species-specific interactions may be  
333 important, whereas at broader spatial scales (i.e., among multiple sites) with large variation in

334 environmental conditions, environmental filtering may be more important (Laliberté *et al.*  
335 2009). Therefore, the importance of biodiversity attributes and environmental conditions for  
336 CSU may vary with spatial scale. We found that for both carbon stocks and uptake, the effects  
337 of taxonomic diversity, vegetation structure and environmental conditions were more often  
338 important at broader scales (i.e., all scales beyond local site-studies, e.g. Chisholm *et al.* 2013)  
339 than at local scales (e.g., van der Sande *et al.* 2017a, Fig. 2a and b). Effects of community-  
340 mean traits on carbon uptake were more often important across sites at regional and global  
341 scales than within sites at local scales, whereas community-mean trait effects on carbon  
342 stocks were not sensitive to scale. Trait diversity was more often important for stocks and  
343 uptake at local scales. It could be, however, that part of the differences between broad and  
344 local scales is due to the generally larger sample size and sampled forest area in broad-scale  
345 studies (on average 217 ha, compared to 9 ha for local-scale studies). Interestingly, our results  
346 do not agree with studies that evaluate different plots sizes, which find stronger relationships  
347 in small compared to large plots (Chisholm *et al.* 2013, Poorter *et al.* 2015). This indicates  
348 that scale effects depend on the measure of spatial scale considered – extent (used here) or  
349 grain size – and that we need studies that explicitly evaluate the role of different measures of  
350 scale on biodiversity-CSU relationships. Hence, the scale-dependence of the biodiversity-  
351 CSU relationship depends on the biodiversity attribute, but seems to be generally stronger at  
352 broader spatial extents and at small grain sizes (e.g. plot size).

353 *Biodiversity-CSU relationship at different management intensities* – We hypothesized  
354 that biodiversity effects on CSU may be more frequently found in disturbed forests and  
355 plantations, where overall diversity and functional redundancy may be lower than in mature  
356 forests without recent anthropogenic disturbance (see also Hooper *et al.* 2005). We found,  
357 however, that biodiversity was less often significantly related to CSU in plantations and  
358 disturbed forests than in mature forests, especially for carbon uptake (Fig. 2c and d). Possibly,

359 the strong differences in light availability among forests with different disturbance intensities,  
360 and among plantations with different stem densities, may be so important for CSU that it  
361 overwhelms the effect of taxonomic diversity. Alternatively, lower diversity and structural  
362 complexity in plantations and disturbed forests could lead to less complementarity and thus  
363 lower importance of diversity. Strong diversity effects on CSU have been widely documented  
364 by theoretical, experimental, and observational studies mainly in temperate grasslands  
365 (Tilman *et al.* 2014). Here, we show that this relationship also applies to tropical plantations,  
366 disturbed forests, and especially to mature tropical forests.

367 *Biodiversity-CSU relationship evaluated by different analytical approaches* – The  
368 studies included in this review used a range of analytical approaches that are likely to affect  
369 the observed biodiversity-CSU relationship. For example, independent effects of biodiversity  
370 on CSU can only be evaluated when controlling for possible confounding factors, such as  
371 variation in environmental conditions. In the studies reviewed here, biodiversity attributes  
372 more frequently affected CSU when analysed separately than when analysed together with  
373 other environmental variables, as for example in a multiple regression analysis (Fig. 2e and f).  
374 This suggests that some of the biodiversity-CSU relationships are correlative associations  
375 rather than causal relationships, although a large part of the relationships still shows effects of  
376 biodiversity attributes on CSU when environmental conditions are accounted for (on average  
377 83% for stocks and 41% for uptake). Hence, for a full understanding of underlying drivers and  
378 independent biodiversity effects on CSU, a more complete and mechanistic framework is  
379 needed that includes multiple biodiversity and environmental drivers and their mutual  
380 relationships.

381

382 **Synthesis of biodiversity–CSU relationships**

383 *How important is biodiversity for CSU?* – A significant relationship between biodiversity  
384 attributes and carbon stocks or uptake was observed in 64% of the relationships. Therefore,  
385 these results extend the findings from experimental studies and temperate ecosystems that  
386 **biodiversity, defined as both the average and variability in vegetation attributes, matter**  
387 **for ecosystem functioning in highly diverse tropical forests.**

388 *Which biodiversity attributes matter for CSU and under what conditions?* – Our  
389 results indicate that not only species diversity, but a suite of biodiversity attributes (taxonomic  
390 and trait diversity, community-mean trait values, and structural attributes, Table 1) are  
391 important for CSU. *Variability* in vegetation attributes (species and trait diversity) most often  
392 positively related with carbon uptake, whereas *average* vegetation attributes (community-  
393 mean traits and structural attributes) most often related with carbon stocks. Variability in  
394 vegetation attributes and average vegetation attributes have thus complementary effects on  
395 CSU. Our results also indicate that the biodiversity-CSU relationship is stronger at larger  
396 spatial scales, possibly because of greater variation in species diversity and other biodiversity  
397 attributes across these larger environmental gradients. Furthermore, the biodiversity-CSU  
398 relationship was strongest in mature forests, possibly because of higher diversity and  
399 structural complexity leading to greater complementarity. These results, however, are based  
400 on relatively few studies, indicating that we need more detailed understanding of which  
401 biodiversity attributes matter, for which CSU variables, and under what conditions. In  
402 summary, **the biodiversity-CSU relationship tends to be weaker in disturbed forests and**  
403 **at local scales, and stronger in mature forests and across larger (e.g. continental) spatial**  
404 **scales.**

405 *Which ecological theories explain biodiversity effects on CSU?* – In this study, we  
406 evaluated several ecological theories that predict how biodiversity can affect CSU (Table 1),  
407 and found that both the quantity (i.e., structural attributes) and also the quality (i.e., taxonomic

408 or trait diversity or community-mean traits) of the vegetation can affect CSU. The traits of the  
409 dominant species were most important for carbon stocks, which is in line with the mass ratio  
410 theory (Grime 1998). Taxonomic diversity was most important for carbon uptake, which  
411 could be explained by a range of diversity theories (i.e., niche complementarity, facilitation,  
412 or dilution of the effects of host specific pathogens). Modelling studies have also shown that,  
413 over the long term (Sakschewski *et al.* 2016) and at a large spatial scales (Loreau *et al.* 2003),  
414 biodiversity enhances ecosystem resilience in the face of environmental change (the insurance  
415 theory, Yachi and Loreau 1999), which assures long-term stability of CSU. Only with  
416 sufficient variation of species and ecological strategies in the plant community does the  
417 community have the potential to adapt to environmental change, in which the rare species of  
418 today could become the dominant species in the future and thus maintain ecosystem  
419 functioning over time. Furthermore, remote sensing studies indicate that biodiversity is also  
420 important for CSU at larger spatial scales (i.e., beyond single site studies), where variation in  
421 environmental conditions and biodiversity attributes increases (e.g., Murray *et al.* 2015).  
422 Hence, **our review and modelling studies highlight three mechanistic reasons (diversity,**  
423 **mass-ratio, and insurance effect) that could explain why biodiversity matters for carbon**  
424 **stocks and uptake at multiple spatial and temporal scales.**

425 *What are the next research steps for improving understanding of biodiversity-CSU*  
426 *relationships?* – We identify three important steps for further research. First, long-term  
427 monitoring of forests that cover a range of spatial scales, environmental conditions and land-  
428 use intensities will be necessary for a better understanding of biodiversity-CSU relationships  
429 in the face of global change (Balvanera *et al.* 2014). Second, to separate the contributions of  
430 biodiversity attributes on CSU from those of environmental conditions, comprehensive and  
431 mechanistic analytical frameworks are needed. Such frameworks should aim to disentangle  
432 different mechanisms underlying CSU and incorporate possible confounding variables. Third,

433 a suite of complementary approaches, such as experiments, empirical field studies, remote  
434 sensing, and modelling can best address the needs for a better understanding of biodiversity-  
435 CSU relationships (van der Sande *et al.* 2017b). The mechanisms behind real-world  
436 biodiversity-CSU relationships can best be evaluated using empirical data, as presented in this  
437 review. To move beyond these predominantly local-scale and short-term studies, we could  
438 make additional use of remote sensing to evaluate the biodiversity-CSU relationship at larger  
439 spatial scales (e.g., Asner *et al.* 2015), and of ecosystem modelling to explore the relationship  
440 at longer temporal scales (e.g., Sakschewski *et al.* 2016). Integrating these approaches will  
441 therefore lead to a more complete understanding of biodiversity-CSU relationships at various  
442 spatial and temporal scales. Consequently, **future research on biodiversity-CSU should**  
443 **focus on long-term forest monitoring, the use of comprehensive analytical approaches to**  
444 **separate biodiversity from other effects on CSU, and on the combination of empirical,**  
445 **remote sensing and ecosystem modelling approaches for a better understanding across**  
446 **spatial and temporal scales.**

447

## 448 **POLICY IMPLICATIONS**

449

450 The findings in this review indicate that different attributes of biodiversity contribute to the  
451 long-term conservation of carbon stocks and to the uptake of carbon from the atmosphere.  
452 These findings have implications for policies related to biodiversity and carbon conservation  
453 in tropical forests. We consider three that are particularly relevant.

454 First, forest-related carbon mitigation policies such as REDD+ would need to **move**  
455 **beyond their current position where biodiversity is considered a ‘nice to have’ (i.e., a co-**  
456 **benefit or add-on), towards incorporating biodiversity as a ‘must have’.** Explicitly  
457 including biodiversity ensures that climate mitigation and adaptation strategies are grounded

458 on ecosystem function, stability and resilience (Christophersen & Stahl 2011, Miles *et al.*  
459 2010, Garcia-Alaniz *et al.* 2017), and that biodiversity conservation is not only based on  
460 moral and ethical justifications. Moreover, it ensures the consideration of a wider range of  
461 biodiversity attributes (e.g. traits versus species richness) in identifying priority areas (Phelps  
462 *et al.* 2012). Such an approach to REDD+ in which carbon and biodiversity are explicitly  
463 combined could simultaneously protect up to 90% of carbon stocks and more than 90% of  
464 biodiversity (Thomas *et al.* 2013).

465         Second, **biodiverse, carbon rich and productive forests should be given priority**  
466 **under the REDD+ framework, especially when threatened by degradation or land-use**  
467 **change**. Data on both carbon stocks and biodiversity attributes could be used to identify  
468 priority REDD+ target areas, allowing alignment of global and national strategies aimed at  
469 maximizing biodiversity and carbon conservation (Phelps, Friess, *et al.* 2012). To keep the  
470 quantification of biodiversity cost-effective, remote sensing based methods, verified by  
471 locally measured biodiversity, can be used to scale to larger areas (Asner 2015, Dutrieux *et al.*  
472 *in review*). At the national scale, countries could prioritize protection of forests rich in carbon  
473 and biodiversity in their Nationally Appropriate Mitigation Actions (NAMAs,  
474 <http://unfccc.int/focus/mitigation/items/7172.php>). At the local scale, because policies  
475 combining carbon and biodiversity conservation may have higher costs (Phelps, Webb, *et al.*  
476 2012), community involvement, strengthening ownership, and the development of pro-  
477 conservation local governance could reduce the costs of monitoring for REDD+ and sustain  
478 long-term biodiversity and carbon conservation initiatives (Gardner *et al.* 2012).

479         Third, forest-related mitigation efforts should **recognize and incorporate a suite of**  
480 **biodiversity attributes as a requirement to maintain and obtain carbon-rich, productive**  
481 **and resilient systems**. Despite policy recognition that biodiversity refers to more than just  
482 species richness, current forest-related carbon mitigation policies rarely incorporate other

483 measures of biodiversity, such as functional traits and community structure. Global and  
484 national efforts to maintain and increase forest cover (through natural regeneration,  
485 restoration, and land use systems that enhance tree cover) under national climate protection  
486 plans, REDD+, the Bonn Challenge, the 2014 UN Declaration on Forests, and the Paris 2015  
487 declaration initiatives could benefit from recognizing a suite of biodiversity attributes. This  
488 would not only strengthen the justification for biodiversity considerations in REDD+, but it  
489 would also promote a more-encompassing understanding of biodiversity and its role in  
490 maintaining ecosystem functions such as carbon stocks and uptake. For example, carbon  
491 stocks and uptake could be maximized through the selection of a large variety of species with  
492 specific desirable traits, manipulated at a range of spatial scales. However, care should be  
493 given to the fact that biodiversity attributes that increase carbon stocks are not necessarily the  
494 same as the ones that increase carbon uptake, and that conserving carbon stocks and uptake  
495 does not necessarily optimize other ecosystem services, or fully support biodiversity at other  
496 trophic levels.

497         Consideration of these policy issues is necessary to realise the full potential of tropical  
498 forests to mitigate climate change through optimizing biodiversity.

499

## 500 **Acknowledgements**

501 The research leading to these results has received partial funding from the European Union  
502 Seventh Framework Programme (FP7/2007-2013) under grant agreement n° 283093 – The  
503 Role Of Biodiversity In climate change mitigatioN (ROBIN). MS and EA received partial  
504 funding through the strategic research program KBIV (KB-14) “Sustainable spatial  
505 development of ecosystems, landscapes, seas and regions”, funded by the Dutch Ministry of  
506 Economic Affairs and carried out by Wageningen University & Research centre (project code  
507 KB-14-003-030), and PB through the projects CB-2015-01 by SEP-CONACYT and IN-

508 211417 by PAPIIT-UNAM. We thank David Makowski for help with the quantitative review,  
509 and Nataly Ascarrunz, Marcel Hoosbeek, Octavio Perez Maqueo, Mauro Garcia-Esteban,  
510 Rodrigo Ferraz, and Andrei Olak for input on earlier versions of the manuscript.

654 **Table 1:** Four biodiversity attributes (taxonomic diversity, trait diversity, community-mean traits, and structural attributes), the ecological  
 655 theories for which they are a proxy and ways to quantify those attributes. The forest structure diagram is obtained from Richards (1996).  
 656

<b>Biodiversity attribute</b>	<b>Taxonomic diversity</b>	<b>Trait diversity</b>	<b>Community-mean traits</b>	<b>Structural attributes</b>
<b>Pictogram</b>				
<b>Ecological theory</b>	Niche complementarity and insurance	Niche complementarity and insurance	Mass-ratio	Vegetation quantity, vegetation distribution
<b>Examples to quantify biodiversity attributes</b>	Taxonomic richness, Shannon-Wiener index, taxonomic evenness	Coefficient of variation in trait values (e.g., wood density, specific leaf area), multivariate trait richness, multivariate trait evenness	Community-mean traits (e.g., wood density, specific leaf area), trait values of the most dominant species	Basal area per hectare, tree density per hectare, canopy height

---

Biodiversity	“The variability among living organisms from all sources including terrestrial, marine, and other aquatic ecosystems and the ecological complexes of which they are part; this includes diversity within species, among species, and of ecosystems” (Convention on Biological Diversity).
Biodiversity attributes	Taxonomic diversity, trait diversity, community-mean trait values, and vegetation structural attributes (see also Table 1).
Carbon uptake	The fluxes in carbon per unit area per unit time (at the ecosystem level). Examples of positive uptake that are mostly included in this review are: total aboveground biomass increase, and growth of recruiting trees. Tree mortality is a negative flux, but was incorporated in some studies to evaluate the net carbon uptake. In this review, carbon uptake is mostly based on positive fluxes. Carbon uptake can be independent from carbon stocks.
Carbon stocks	The amount of carbon (or biomass) per unit area (at the ecosystem level). This carbon can be based on aboveground living biomass, (fine) root biomass, or soil organic matter.
Community-mean traits	Community average trait values, such as specific leaf area, wood density and leaf nitrogen concentration, often weighted by species’ basal area or abundance.
Functional trait	Any measurable characteristic of an individual that is expected to have an effect on one or multiple specific ecosystem processes and is affected by environmental conditions.
Insurance theory	Species respond differently to environmental changes and thus a

	species-rich community insures long-term ecosystem functioning under environmental change (Yachi & Loreau 1999).
Mass-ratio theory	The most dominant species and their traits mostly determine ecosystem processes (Grime 1998). That is, the community-mean (e.g., of trait values, often weighted by species' abundance or basal area) more strongly determines ecosystem processes than diversity (in species or trait values) in the community.
Niche complementarity theory	Species are complementary in their resource acquisition and use. Therefore, high diversity (of species or traits) results in efficient acquisition and use at the community-level, and thus in high carbon stocks and uptake (Tilman 1999).
Remote sensing	Information on biodiversity and CSU obtained from a distance, e.g. by using aircrafts or satellites.
Resilience	The capacity of an ecosystem to return to the pre-condition state following a perturbation, including maintaining its essential characteristics taxonomic composition, structures, ecosystem functions, and process rates (Holling 1973).
Structural attributes	Community-average or community-total values of structural components of the community, such as plot basal area and average stem diameter.
Taxonomic diversity	Variability in species (e.g., the number or diversity) within a community.
Trait diversity (or functional trait diversity)	Variability in trait values within a community. This can be based on multivariate trait diversity and on the variability in individual traits (Table 1).

658 **Table 2:** Results from logistic regression models to evaluate the probability of a significant  
659 relationship between the attributes and carbon stocks or carbon uptake (CSU) as response variable. If  
660 the intercept is significantly positive (i.e., the 2.5% confidence interval (CI) is higher than 0), then the  
661 probability of obtaining a significant relationship is significantly higher than the probability of  
662 obtaining a non-significant relationship. If the intercept is significantly negative (i.e., the 97.5% CI is  
663 lower than 0), then the probability of obtaining a non-significant relationship is significantly higher  
664 than the probability of obtaining a significant relationship. An asterisk ('\*') indicates the significant  
665 intercepts. For taxonomic diversity, trait diversity and structural attributes, we evaluated the  
666 probability of any significant relationship (i.e., either positive and/or negative), a positive relationship  
667 (+), and a negative relationship (-). For community-mean traits, all biodiversity attributes, and  
668 environmental conditions, we only evaluated the probability of any significant relationship. The  
669 column 'Effect is true or false' indicates whether the tested prediction is 'true' (i.e. significant positive  
670 intercept), is 'false' (i.e. significant negative intercept), or is not significant ('ns'). The relationship of  
671 community-mean traits and all biodiversity attributes with stocks have NAs because all reviewed  
672 relationships were significant, and of negative structural attributes effects on stocks because no  
673 relationships were significantly negative. For sample sizes and percentage significant relationships,  
674 see Fig. 2.

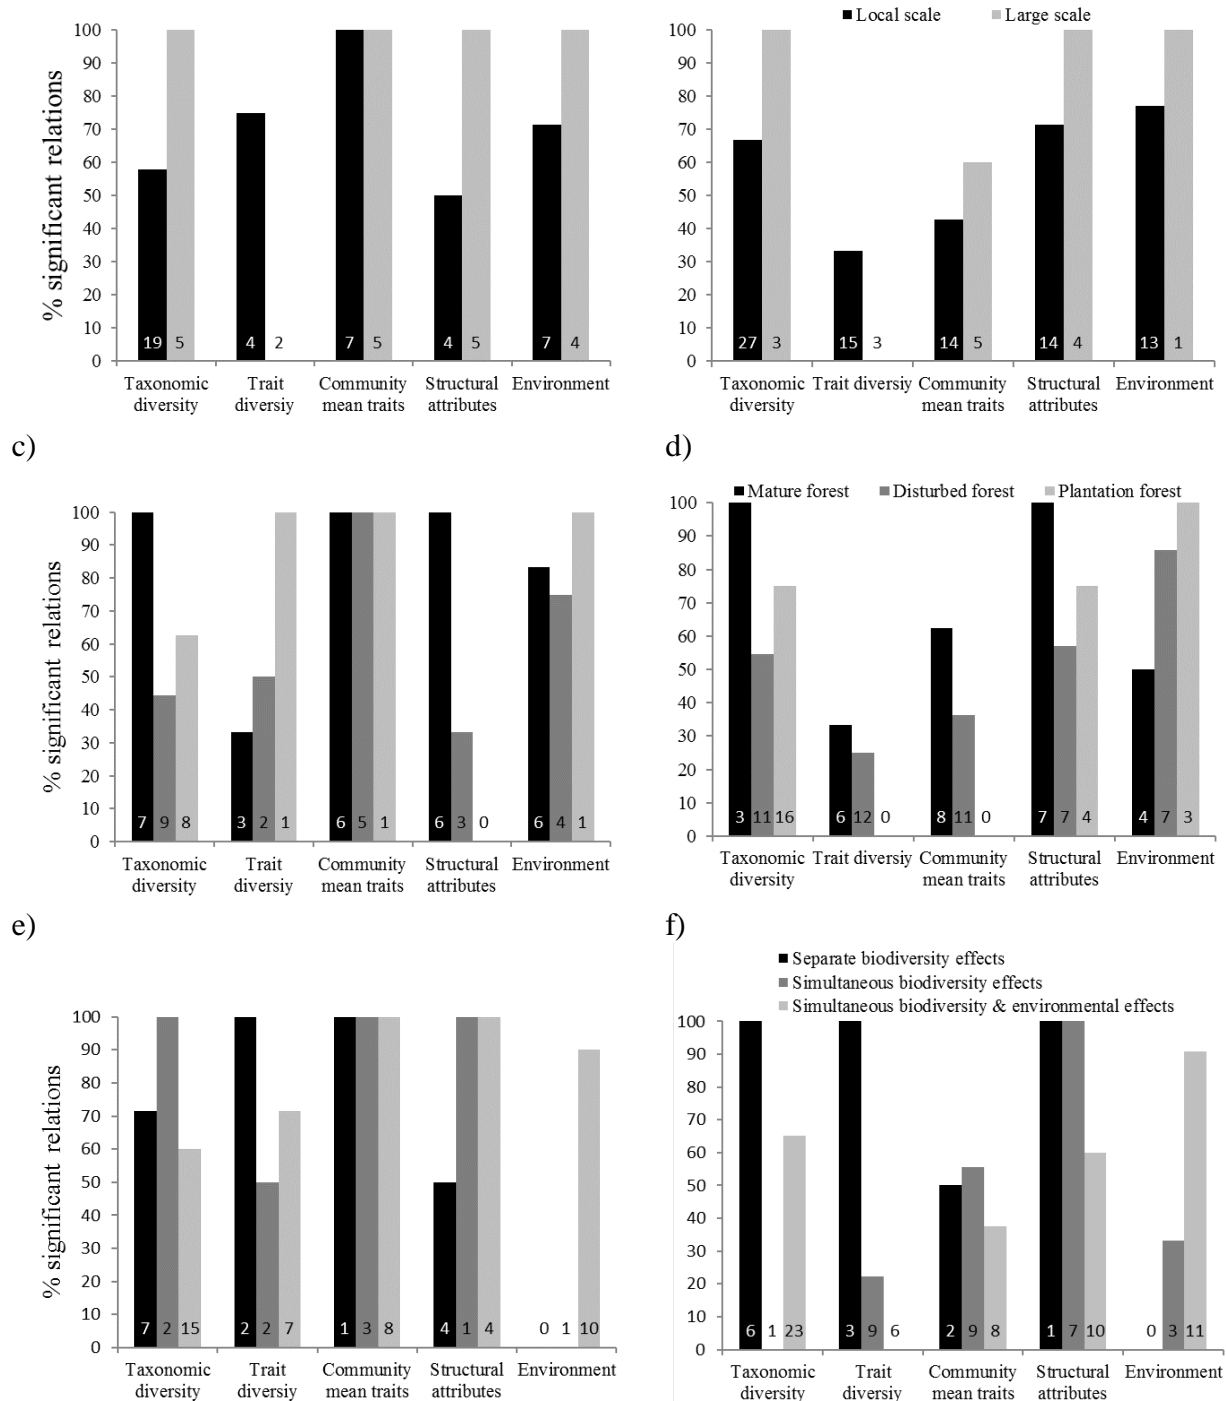

<b>Carbon response variable</b>	<b>Biodiversity predictor variable</b>	<b>Intercept</b>	<b>2.5% CI</b>	<b>97.5% CI</b>	<b>Effect is true or false:</b>
Stocks	Taxonomic diversity +/-	1.64*	1.16	2.19	true
	Taxonomic diversity +	1.42*	0.96	1.93	true
	Taxonomic diversity -	-1.46*	-1.97	-1.00	false
	Trait diversity +/-	-2.41*	-3.09	-1.84	false
	Trait diversity +	-0.32	-1.12	0.45	ns
	Trait diversity -	-0.49	-1.31	0.28	ns
	Community-mean traits	NA*	NA	NA	true
	Structural attributes +/-	3.67*	2.40	5.77	true
	Structural attributes +	3.67*	2.40	5.77	true
	Structural attributes -	NA	NA	NA	ns
	All biodiversity attributes	NA*	NA	NA	true
	Environmental conditions	2.00*	1.24	2.94	true
Uptake	Taxonomic diversity +/-	1.42*	1.03	1.84	true

691 **Figure 2:** Percentage of relationships showing a *significant* effect of four biodiversity  
 692 attribute groups (taxonomic diversity, trait diversity, community-mean traits and structural  
 693 attributes) and environment on carbon stocks (all left panels) and carbon uptake (all right  
 694 panels) in the 38 reviewed studies. Each pair of graphs shows a different grouping of studies:  
 695 (a and b) by scale, comparing local and large spatial scale; (c and d) by management intensity,  
 696 comparing plantation forests, disturbed forests and mature forests; and (e and f) by analytical

697 framework used in the studies: comparing frameworks that use all biodiversity attributes  
698 individually ('Separate biodiversity effects'), multiple biodiversity attributes simultaneously  
699 ('Simultaneous biodiversity effects'), and multiple biodiversity attributes and environmental  
700 variables simultaneously ('Simultaneous biodiversity & environmental effects'). The numbers  
701 in each bar indicate the number of relationships that were evaluated.
