11 Abstract

12 The COVID-19 pandemic continues to strongly affect global energy systems. Global power sector CO₂
13 emissions show a substantial decline, thanks to a) the COVID-19-induced economic downturn and
14 resulting reduction of electricity demand and b) a decrease of carbon intensity of power generation
15 as coal generation is decreased most strongly. These effects illustrate the opportunity for different
16 policies to support a structural and accelerating decline of power sector emissions.

17 Main

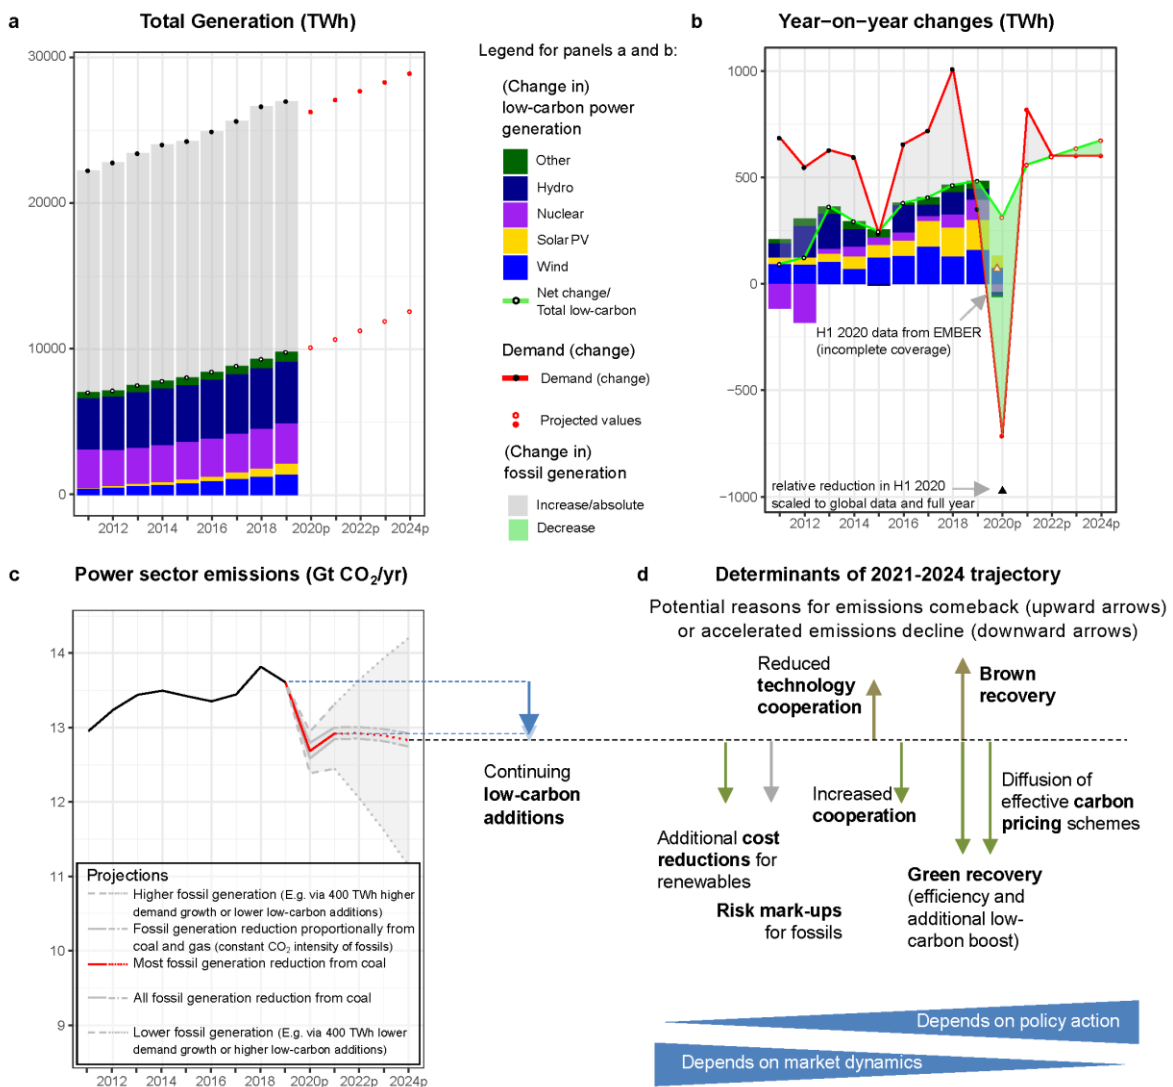

18 Even before the COVID-19 pandemic and its impact on the energy system and CO₂ emissions¹, the
19 power sector was amidst a dynamic transformation process. While fossil fuels (predominantly coal
20 and gas) generate most power in most countries, renewable energies dominate growth of global
21 power generation (Fig. 1a and b, and Extended Data Fig. 1). The uptake of wind and solar has been
22 concentrated in a few markets with substantial support policies in place in the early 2010s, but has
23 become much more wide-spread in recent years after continued reductions in technology costs and
24 improvement in performance².

25 In this situation, the moderate reduction in electricity demand, stemming both from the direct
26 restrictions in industry, commerce, and other activities and from the overall economic downturn, has
27 had a particularly strong impact on power sector emission. Real-time generation data by fuel up to
28 end of September is available for India³, USA⁴ and Europe⁵, which together accounted for 34% of
29 global 2019 CO₂ emissions from power generation⁶. In these three markets, monthly electricity
30 demand has declined by up to 20% compared to 2019, while the monthly CO₂ emissions from the
31 power sector have decreased by up to 50% (Fig. 2). The reason is the so-called merit-order of the
32 capacity mix of different generation technologies. If demand decreases, plants with the highest
33 variable costs are switched-off first. Fossil-based power plants incur costs from burning fuels to
34 generate electricity. Costs of renewable and nuclear power are dominated by the construction of the
35 plants, so these technologies are characterized by low variable costs per kWh and thus operate even
36 with the reduced demand. This merit order mechanism induces an asymmetry against fossil fuels in
37 the electricity generation mix and therefore CO₂ emissions decrease stronger than electricity
38 demand.

39 Even within fossil generation, reductions in coal power generation are currently higher than
40 reductions in power generation using natural gas (Extended Data Fig. 2), increasing the down-ward
41 trend of coal in OECD countries. This is counter-intuitive, as traditionally natural gas power plants are
42 thought to be less favorably placed on the merit-order, due to higher fuel costs. The overall
43 economic downturn has however reduced demand for oil and natural gas in all sectors, so that spot-
44 market prices for gas have declined, favoring gas-powered generation. Coal prices have also declined,
45 but with a smaller impact on variable costs of coal-based power generation – due to higher shares of

46 extraction and transportation related costs as well as higher maintenance costs. The effect of coal-to-
 47 gas switching has additionally been supported in Europe by relatively stable emission prices in the EU
 48 Emissions Trading System (EU-ETS), which has contributed further to unfavorable economics for coal-
 49 based power generation⁷.

50 With assumptions on 2020 demands based on IMF GDP projections⁸ and reduced yearly addition of
 51 low-carbon generation (Figure 1b), we estimate yearly CO₂ emissions from the power sector to be
 52 6.8% [4.9-9.0%] lower than in 2019 (Fig. 1c). This is much higher than previously estimated by Le
 53 Quéré et al. (1.5% [0.3%-3.1%] power sector emission reduction in their scenario S3, see also
 54 Methods), and roughly in line with an updated version of their daily model that we calibrated to the
 55 observed emission reductions in Europe, India and the US until end of September (Supplementary
 56 Fig. S2), estimating yearly reductions of 7.5% [5.3-10.1%] for the power sector (see SI). The global
 57 reduction results from strong reductions of fossil generation in most countries, partly offset by
 58 increases in China (Extended Data Fig. 1). As a result, the share of China in global power system CO₂
 59 emissions strongly increases in 2020, from 37 % in 2019 to 39%.

60

61 **Figure 1: Historical evolution of global power generation and CO₂ emissions, and projections until 2024.** a) Absolute
 62 values for each year, with low-carbon technologies shown separately (colored bars) and aggregated (circles). b) Year-on-
 63 year changes of power generation by individual low-carbon technologies (colored bars), their total net change (white dots
 64 and green line), and total power generation as proxy for demand (black dots and red line). The shaded areas indicate
 65 increases of residual fossil generation (grey) and decreases (green). c) Power sector emissions from 2011-2019, and
 66 projections for 2020-2024 based on the power system evolution in panels a) and b) (please note that the y-axis scale does

67 *not start at zero). d) Qualitative analysis of key factors determining the near-term evolution of global power sector CO₂*
68 *emissions. For details on data sources and projections, see Methods.*

69 If the annual net addition of low-carbon generation (from wind, solar, nuclear, and hydro power
70 generation) surpasses the increase in power demand, total fossil generation decrease. During most
71 of the last decade, annual demand growth slightly surpassed additional generation of low-carbon
72 power, except for 2015 and 2019 (see Fig. 1b). The central estimate of the latest World Economic
73 Outlook by the IMF⁸ projects 2021 GDP levels to be equal to the 2019 level, after a strong dip in
74 2020. Based on the strong coupling between economic growth and power demand (Supplementary
75 Fig. S3), electricity demand is likely to remain at or below 2019 levels at least until the end of 2021.
76 On the other hand, the build-up of low-carbon power capacity is expected to continue in the near
77 and longer term future, with only a slight deceleration in 2020, mostly caused by reduction of nuclear
78 generation in Europe⁹. This leads to continuing decrease of emissions intensity per kWh of power
79 generation, with a steep drop in 2020 (Extended Data Fig. 3). To the extent that the growth in low-
80 carbon power generation exceeds future demand increases, power supply emissions may have
81 reached their all-time peak in 2018 (central estimate in Fig. 1c). Power sector emissions in 2021 will
82 likely increase compared to 2020, but remain below 2019 values, given continuing additions of low-
83 carbon generation (Fig. 1c, blue arrow).

84 If the rate of low-carbon additions increases through 2022 and beyond, and assuming that demand
85 growth rates in 2022-2024 are back to average levels over past years (which are similar to near-term
86 yearly increases expected by IEA¹⁰), a cross-over point would be reached. Passing this point would
87 mean a structural transition from growing to decreasing fossil power generation. CO₂ emissions
88 would thus decline from 2018 onwards based on underlying drivers, accelerated by the COVID-19
89 pandemic. If demand increases faster, or low-carbon growth slows considerably, fossil fuel
90 generation and emissions could continue to increase through 2024, but would reach the 2018 peak
91 level only with very high demand increases or very low additions of low-carbon generation.

92 Fig. 1c contrasts the central estimate, assuming the demand and low-carbon additions as in panels a
93 and b, and assuming constant emission intensity of fossil power generation, with alternative
94 projections. These vary the carbon intensity of fossil generation, and the overall amount of fossil
95 generation (which given the merit order structure is determined by both absolute power demand
96 and low-carbon generation). Emissions could revert back to levels of the 2018 peak by 2024 if
97 demand increases are 400 TWh per year higher (or annual low carbon additions 400 TWh lower, or
98 any combination leading to a 400 TWh/yr net difference for fossil generation), while very fast
99 emissions decline is possible if demand increases are 400 TWh lower per year (or low carbon addition
100 400 TWh higher).

101 Various market factors affects the projections (Fig. 1d). A disruption in supply chains, reduced
102 availability of capital investments and reduced international technology cooperation would hurt low
103 carbon power addition and deployment of energy efficiency technologies, especially in emerging
104 economies¹¹. Existing plans to expand the fleet of coal-based power plants¹² face very immediate
105 risks of resulting in stranded assets, both due to fast technological change and climate change
106 considerations^{13,14}. The current situation illustrates the weakening market position of coal-power
107 generation- suffering simultaneously from reductions in power prices and from an unfavorable
108 position on the merit order compared to low-carbon alternatives, resulting in strongly reduced
109 market shares. This demonstration of low resilience of coal will make it more difficult for future
110 projects to access financing, in turn increasing the attractiveness of low-carbon projects. Lastly, any
111 delay of investment decisions for power generation expansion makes renewable energy projects
112 more attractive, as costs of wind, solar, and storage¹⁵ continue to decrease.

113
 114 **Figure 2: 2020 values of monthly power demand (x-axis) and emissions (y-axis), relative to 2019.** Emissions calculated
 115 from fossil generation data by fuel for European countries with highest power sector emissions from ENTSO-E. Indian data
 116 from carbontracker.in. US data from EIA, calculated from fossil generation data by fuel. February data is adjusted to
 117 account for the leap year 2020.

118 It is clear that the post-crisis developments will be strongly impacted by near-term policy choices.
 119 There is a distinct risk that brown recovery packages will give support to construction of additional
 120 fossil-fueled power plants. These are, however, very risky investments, as the rate of utilization of
 121 coal power plants has been decreasing in nearly all markets over the past years and has plummeted
 122 amid the pandemic in 2020⁹ (see above). Only with very strong rebound of demand, supported by
 123 indiscriminate support also for inefficient industries, will fossil generation be able to expand back to
 124 2018 levels, but would be the first to lose market shares in repeated suppression of demand, both
 125 due to crises or increased efficiency.

126 Inversely, the current situation offers a unique opportunity for policy-makers to make the decreasing
 127 trend in power sector emissions irreversible, while total electricity generation continues to grow. The
 128 most effective means for accelerating the transformation of the power system is to strengthen
 129 carbon pricing around the world and eliminating subsidies for fossil fuels. The current situation of
 130 very low fossil fuel prices offers a good opportunity for these measures, especially if revenue
 131 recycling is used to support other societal goals¹⁶. Experience from the UK minimum price and recent
 132 auction price increases in the EU-ETS show that moderate carbon prices of around 20 \$/t CO₂ are
 133 already effective in reducing power sector emissions considerably^{7,17}. An important characteristic of
 134 carbon pricing, making it indispensable in the medium-term, is that it counteracts the consumer price
 135 reductions of fossil fuels resulting from their reduced usage¹⁸.

136 A complementary way to support power sector decarbonization can make use of the merit order
137 mechanism described before. Supporting investments in low-carbon power generation, especially
138 fast-growing granular power technologies like wind and solar¹⁹, and increasing energy efficiency
139 reduces the residual demand for fossil power generation. Both these measures have the additional
140 benefits of high readiness, fast scalability, high employment intensities and local value added.
141 Furthermore, policies supporting behavioral, social, and structural changes reduce energy demand
142 for attaining service levels and thus reduce future electricity demand growth²⁰, resulting in decreased
143 import bills for energy importers.

144 International cooperation is key to help fast growing economies outside the OECD to quickly scale-up
145 these two options, thus also reaching peak emissions as soon as possible (Extended Data Fig. S1) and
146 avoid additional carbon lock-in. Long-term investments funds (supported for example by the EU)
147 could provide credit below the high market interest rates in developing countries, thereby reducing
148 the high capital costs of low-carbon power generation technologies and investments in energy
149 efficiency. These support schemes should incentivize developing countries to introduce carbon
150 pricing schemes in order to avoid risky rebound effects at all scales, by which depressed world
151 market prices of fossil fuels could lead to increased use of these fuels in unregulated regions²¹ and
152 sectors²². If designed properly, these schemes can enhance international cooperation significantly²³,
153 and contribute to fostering sustainable development post COVID-19 globally.

154 The power sector has a crucial role for the decarbonization of the entire energy system, and has
155 already been in the midst of a dynamic transformation process before COVID-19. The economic
156 repercussions of the pandemic have led to a very pronounced reduction of fossil-fuel based power
157 generation, illustrating the risks of stranded assets in coal power generation to financial actors.
158 While the uncertainties on near-term projections are considerable, it is possible that power sector
159 CO₂ emissions will not come back to their level of 2018²⁴. Various policy instruments could be
160 effective in supporting an accelerated emissions decline over the next few years.

208 Methods

209 Historic data

210 The analysis builds upon yearly power generation data until 2019 from BP⁶. Power sector data from
 211 EMBER for the first half of 2020 for a subset of countries, roughly representing $\frac{3}{4}$ of global power
 212 generation is shown in Fig. 1b) for comparison⁹. Data on CO₂ emissions for 2011–2018 is from IEA¹⁰,
 213 and 2019 data is deduced from the generation data in the BP dataset, assuming constant emission
 214 factors by fuel.

215 Projections based on yearly generation estimates

216 The projections of total demand (and total power generation) in 2020 and 2021 is based on GDP
 217 projections by IMF⁸, assuming an elasticity of electricity demand to GDP of 0.6.
 218 Demand projections for 2022–2024 assume the average value of 2011–2019 demand increases,
 219 resulting in a number comparable to yearly demand increases in the IEA’s stated policies scenario¹⁰.

220 The projections for increased generation from low-carbon technologies for 2020–2024 assume a
 221 continuation of the linear trend observed from 2017–2019, with a once-off 40% reduction in the year
 222 2020 to account for the reduced output of nuclear power plants observed in the data for the first half
 223 of 2020, as well as interruptions in renewable installations in March and April.

224 For the projection of emissions in 2020–2024, we distinguish between uncertainty about volumes of
 225 fossil generation (being determined by growth of total demand and low-carbon generation), and
 226 uncertainty about composition and thus emission intensity of fossil generation (being a question of
 227 relative prices). The central three trajectories (red and inner grey lines) all are based on the central
 228 estimate on development of fossil generation as displayed in Figure 1, panels a and b. The higher
 229 grey line assumes the emissions intensity of fossil generation to stay constant at 2019 levels, as used
 230 in previous studies²⁵, while the lower grey line assumes all generation reductions to be taken up by
 231 coal generation, which seems to be more in line with data from the US, India and Europe (Extended
 232 Data Fig. 2). The central red line takes an intermediate assumption, namely that the emissions
 233 intensity of displaced fossil generation is the mean between the intensity of fossil generation and
 234 coal power generation. Additionally, a very high (and a very low) emission estimate result from
 235 assuming fossil generation to be higher (or lower) than in the central estimate, by 200/400/800/1200
 236 and 1600 TWh in years 2020–2024 respectively. This reflects the uncertainties about growth of both
 237 demand and low-carbon generation, which is in the order of few hundreds of TWh each and

238 increases over time. The very high estimate assumes constant emission intensity of fossil generation,
239 while the very low one assumes all reductions to be from coal generation. Average emissions
240 intensities of generation for both gas and coal are assumed to remain at 2019 levels, while in reality
241 might continue to improve in 2020 over the next years, due to higher variable generation costs of
242 older and less efficient plants.

243 [Comparison with estimates from daily model based on confinement by Le Quéré et al.](#)
244 The original model by Le Quéré assumed no emission reductions for the power sector for level 1
245 confinement in neither the low, medium or high specification. We have replicated a simpler version
246 of their model (without disaggregation of China and the US) that – using their specification - is able to
247 replicate the economy-wide yearly reductions mentioned in their paper, and used this to calculate
248 the power sector emission reductions mentioned above in the main text (as the paper and SI of Le
249 Quéré, while showing them in graphs, do not specify numbers on relative yearly reduction per
250 sector). We then adjusted the specifications on sectoral reduction per confinement level (Tables
251 S1,S2) to match the observed emission reductions in the power sectors of the EU, India and the US
252 (Supplementary Figs. S1,S2), arriving at an update estimate broadly matching the alternative top-
253 down methodology from Fig. 1.

254 Further details on the projections in Figure 1 and comparisons with different specifications of the
255 daily model from Le Quéré et al. 2020 can be found in the Supplementary Information.
