Keywords: energy and carbon footprints; inequality; energy for decent life; 1.5 degree target, Europe

Abstract: The call for a decent life for all within planetary limits poses a dual challenge: Provide all people with the essential resources needed to live well and, collectively, not exceed the source and sink capacity of the biosphere to sustain human societies. We examine the corridor of possible distributions of household energy and carbon footprints that satisfy both minimum energy use for a decent life and available energy supply compatible with the 1.5°C target in 2050. We estimated household energy and carbon footprints for expenditure deciles for 28 European countries in 2015 by combining data from national household budget surveys with the Environmentally-Extended Multi-Regional Input-Output model EXIOBASE. We found a top-to-bottom decile ratio (90:10) of 7.2 for expenditure, 3.1 for net energy and 2.6 for carbon. The lower inequality of energy and carbon footprints is largely attributable to inefficient energy and heating technologies in the lower deciles (mostly Eastern Europe). Adopting best technology across Europe would save 11 EJ of net energy annually, but increase environmental footprint inequality. With such inequality, both targets can only be met through the use of CCS, large efficiency improvements, and an extremely low minimum final energy use of 28 GJ per adult equivalent. Assuming a more realistic minimum energy use of about 55 GJ/ae and no CCS deployment, the 1.5°C target can only be achieved at near full equality. We conclude that achieving both stated goals is an immense and widely underestimated challenge, the successful management of which requires far greater room for maneuver in monetary and fiscal terms than is reflected in the current European political discourse.

39 Introduction

40 Decarbonising the energy system in accordance with the Paris Agreement
41 requires a deep transformation of both the supply and the demand side
42 (1,2). On both sides, however, necessary transformation is restricted by
43 different factors. On the supply side, there exist economic and physical
44 upper limits of how much energy can be provided from renewable sources
45 by 2050 on the one hand, and how much CO₂ removal infrastructure is used
46 to compensate for remaining emissions from fossil fuels on the other. On
47 the demand side (3), by contrast, there are lower bounds on how much
48 energy is minimally required for a decent standard of living (2,4),
49 depending on existing non-energy infrastructures and services and
50 assumptions about their future transformation (3), as well as the prevalent
51 social ideas about what constitutes a decent life (4,5). Maximum energy
52 supply and minimum energy use describe the corridor in which the
53 simultaneous achievement of climate targets and a decent standard of living
54 for all is possible and, at the same time, restricts the distribution of
55 available energy services among the population. If this dual objective is
56 taken seriously in European climate policy, then there are practical limits to
57 how unequal the society of the future can be, which go beyond the purely
58 political (6). In fact, a limited energy supply creates an obvious, if rarely
59 acknowledged, zero-sum game where energetic over-consumption by some
60 must be compensated by less consumption by others.

61 In Europe, the differences in household energy and carbon footprints are
62 large within and between different regions (7-9). Final energy footprints
63 ranged from less than 50 GJ per capita to over 200 GJ per capita in 2011
64 (9), and carbon footprints from below 2.5 tCO₂eq per capita to 55 tCO₂eq
65 per capita (10). The published 1.5°C global decarbonisation scenarios also
66 show very large differences in the assumed average per capita final energy
67 consumption (15-100 GJ/capita) in 2050, depending on assumptions about
68 how much energy is needed for a decent life, or how large the future supply
69 will be (1,2,4).

70 In this paper, we assess under what conditions European energy use
71 inequality is compatible with the achievement of global climate goals and a
72 decent standard of living, taking both inequality within and between
73 European countries into account. We analyze the distribution of energy and
74 carbon footprints and intensities across European expenditure deciles and
75 final consumption categories in 2015, and compare this structure to a
76 counterfactual, where all European expenditure deciles use the best
77 technology available in Europe in 2015. Finally, we examine how the energy
78 inequality across European expenditure deciles would need to change in
79 order to achieve the dual goal of climate protection and a decent standard
80 of living for all.

1
2
3 81 While the European Green Deal recognizes that inequalities in income,
4 82 energy infrastructure, energy consumption, and carbon emissions, lead to
5 83 different responsibilities and capacities in achieving the energy and
6 84 emission savings targets (11), a quantification of the corridor for a 1.5°C
7 85 compatible and just transition in Europe is missing in the literature.
8
9

10 11 86 **Materials and methods**

12 13 87 **Income-stratified national household energy and** 14 88 **carbon footprints**

15
16
17 89 We used the Environmentally-Extended Multi-Regional Input-Output (EE-
18 90 MRIO) model EXIOBASE for 2015 (version3.7, industry-by-industry) (12)
19 91 and the European national household budget survey (HBS) macro-data from
20 92 EUROSTAT for 2015 (13) to calculate income-stratified national household
21 93 energy and carbon footprints (together denoted as environmental footprints
22 94 in this paper). The EUROSTAT HBS publishes mean household expenditure
23 95 by income quintile, in purchasing power standards (PPS), by COICOP
24 96 consumption category, country and year. We chose EXIOBASE as the EE-
25 97 MRIO for this study because of its European focus, with nearly all countries
26 98 in the EUROSTAT HBS also found as stand-alone countries in EXIOBASE,
27 99 its detailed sectoral resolution and environmental extension data, and its
30 100 year coverage.
31

32 101 To integrate HBS data into EXIOBASE we created correspondence tables
33 102 between the EXIOBASE sectors and the matching COICOP consumption
34 103 categories used in the HBS. To this end we used the relative expenditure
35 104 shares of each income quintile on the COICOP consumption categories in
36 105 the HBS to disaggregate the matching EXIOBASE national household final
37 106 demand expenditure per sector by income quintile. Using standard input-
38 107 output techniques we calculated 'total' (i.e. direct and indirect supply chain)
39 108 energy and carbon intensities per EXIOBASE sector, and multiplied them
40 109 with the income-stratified EXIOBASE national household final demand
41 110 expenditure, to estimate the supply chain part of national household energy
42 111 and carbon footprints by national income quintile.
43
44

45 112 We report energy footprints based on two different energy indicators. In our
46 113 empirical results (Figures 1 to 3) we use the extension 'energy carrier net:
47 114 total' from EXIOBASE, which includes final energy use and losses (14,15).
48 115 This energy indicator represents primary energy and the resulting footprint
49 116 is termed 'net energy footprint' in the rest of the paper. We use this
50 117 indicator to capture the heterogeneity in the efficiency of energy supply and
51 118 demand technologies across expenditure groups. For the calculation of the
52 119 corridor (Figure 5) we use net energy without losses, which represents final
53 120 energy, to be compatible with the supply and demand scenarios from the
54
55
56
57
58
59
60

1
2
3 121 literature, which report final energy. The results from this indicator are
4 122 termed 'final energy footprint.' Please note that the primary and final
5 123 energy extensions we used in the model are not strictly equivalent to the
6 124 indicators total primary energy supply and final energy from international
7 125 energy statistics, because the former apply the residence principle while
8 126 the latter apply the territorial principle (12,16).

9
10
11 127 For calculating the carbon footprint, we used the EXIOBASE greenhouse
12 128 gas (GHG) emission extensions CO₂, CH₄, N₂O, SF₆, HFCs, and PFCs (all
13 129 in CO₂-equivalent), from combustion, non-combustion, agriculture and
14 130 waste, but not land-use change (12). Direct household energy use and
15 131 carbon emissions are included in the environmental footprints.

16 17 18 132 **European household expenditure deciles**

19
20 133 To calculate European household expenditure deciles, we first ranked the
21 134 population weighted national income quintiles (140 in total: 28 European
22 135 countries x 5 national income quintiles each) according to their mean
23 136 household expenditure in PPS, and then aggregated the result to 10
24 137 European expenditure groups. For brevity we call these expenditure
25 138 deciles, or simply deciles, through the rest of the paper. Our coverage of
26 139 European countries is limited to those with data available in both the
27 140 EUROSTAT HBS and EXIOBASE. This resulted in a country sample for 2015
28 141 that includes the non-European Union (EU) members, Norway and Turkey,
29 142 and excludes the EU members Italy and Luxembourg.

30 31 32 143 **Units of analysis**

33
34
35 144 The unit of analysis for our energy and carbon footprint calculations is the
36 145 household. We normalized our results to average adult equivalent per
37 146 household, as this is the method used in the EUROSTAT HBS to account for
38 147 different household sizes. The first adult in the household is given a weight
39 148 of 1.0, each adult thereafter 0.5, and each child 0.3 (17).

40
41 149 To calculate the corridors for achieving the dual goal of climate protection
42 150 and a decent standard of living for all, we converted the total (economy-
43 151 wide) per capita final energy values from the scenario literature to
44 152 household final energy footprints per adult equivalent using the following
45 153 factors: For the average European share of total final energy footprint
46 154 attributable to households in 2015, we used the factor 0.65, and for the
47 155 average European adult equivalent to population ratio in 2015, a factor of
48 156 0.63 (see supplementary information (SI), 'Units of analysis' section).
49 157 Numerically this results in almost identical values for per capita final
50 158 energy and household final energy footprints per adult equivalent.

51
52
53
54 159 Estimates of minimum final energy use for a decent life are from (2) and (4),
55 160 while maximum supply of decarbonised final energy compatible with the
56
57
58
59
60

1
2
3 161 1.5°C (and 2°C) target is from the decarbonisation scenarios in the
4 162 International Institute for Applied Systems Analysis (IIASA) scenario
5 163 database (1,18).

7 164 As inequality measure we use the 90:10 ratio, i.e. the expenditure or the
8 165 environmental footprint of the top European expenditure decile divided by
9 166 that of the bottom European expenditure decile. Thus, an expenditure 90:10
10 167 ratio of 5 means that one adult equivalent in the top decile spent 5 times
11 168 more on average than one adult equivalent in the bottom decile.

14 169 **Counterfactual**

16 170 We construct a counterfactual energy distribution which applies the
17 171 empirical best technology available in 2015 to remove differences in the
18 172 efficiencies of energy supply and use across all expenditure deciles. Based
19 173 on this, we calculate for each value combination of maximum final energy
20 174 supply from four 1.5°C and one 2°C supply scenarios (1,18) and minimum
21 175 energy use from two 1.5°C compatible demand scenarios (2) and (4), the
22 176 maximum possible inequality as 90:10 ratio, in a way that preserves the
23 177 relative distance between the deciles. All data, formulas and procedures are
24 178 described in more detail in the SI.

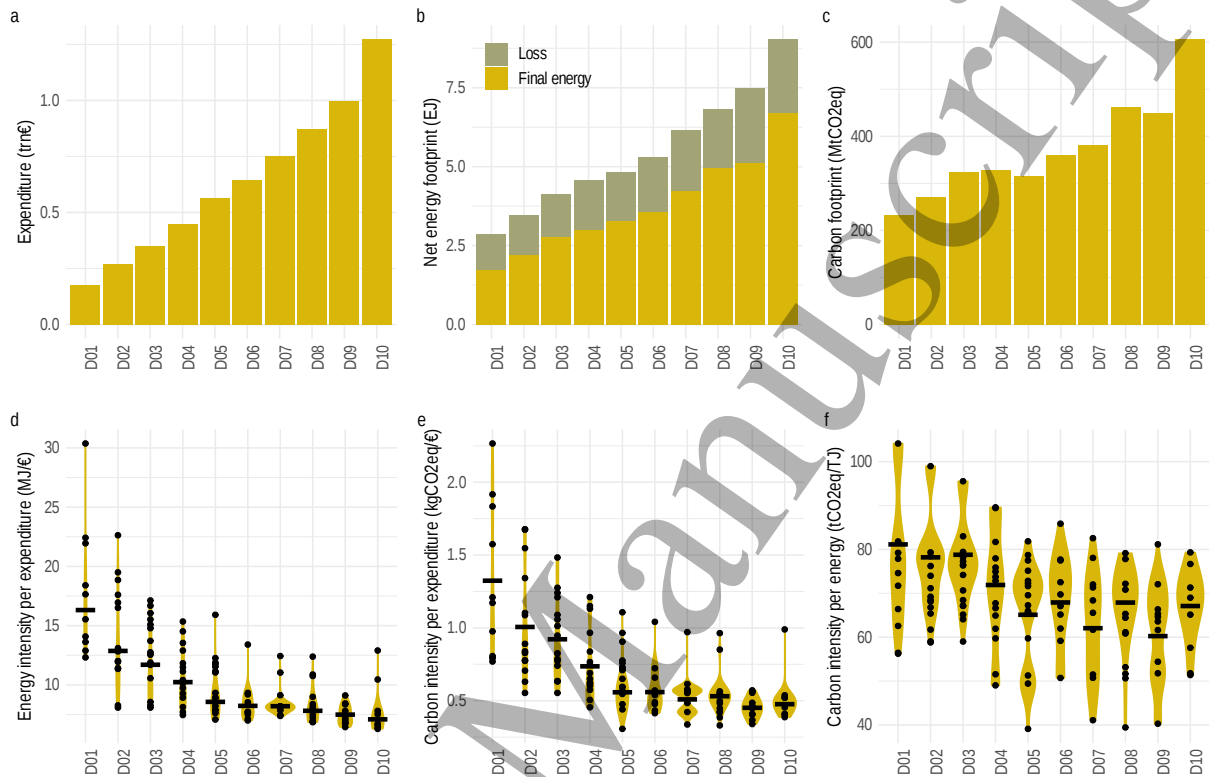

29 179 **Results and discussion**

31 180 **Environmental footprints are less unequal than** 32 181 **expenditure**

35 182 Increasing expenditure generally translated into larger environmental
36 183 footprints across European expenditure deciles (Figures 1a-c). However, the
37 184 energy and carbon inequality was much lower than the expenditure
38 185 inequality, corroborating previous results (19). In our sample the top-to-
39 186 bottom decile (90:10) ratio was 7.2 for expenditure, 3.1 for net energy and
40 187 2.6 for carbon. Total expenditure ranged from 0.2 trn€ to 1.3 trn€ between
41 188 bottom and top decile, or 5263€ to 38110€ per adult equivalent (ae), the net
42 189 energy footprint from 2.9 EJ to 9.0 EJ (or 86 GJ/ae to 270 GJ/ae), and the
43 190 carbon footprint from 233 MtCO₂eq to 607 MtCO₂eq (or 7.0 tCO₂eq/ae to
44 191 18.1 tCO₂eq/ae).

47 192 The reason for this is evident from Figures 1d-f. Both the energy intensity of
48 193 consumption, measured as net energy footprint per € expenditure (d), and
49 194 the carbon intensity of energy, measured as carbon footprint per net energy
50 195 footprint (f), decreased from bottom to top expenditure decile. The average
51 196 net energy intensity of consumption decreased from 16.3 MJ/€ in the bottom
52 197 decile to less than half (7.1 MJ/€) in the top decile. Likewise, the average
53 198 carbon intensity of net energy was higher in the bottom decile (81
54 199 tCO₂eq/TJ) compared to the top decile (67 tCO₂eq/TJ). The carbon intensity

200 of consumption in Figure 1e combines the effects of the intensities
 201 displayed in Figures 1d and 1f. For all intensities, the variance is highest in
 202 the bottom deciles (Figures 1d-f).

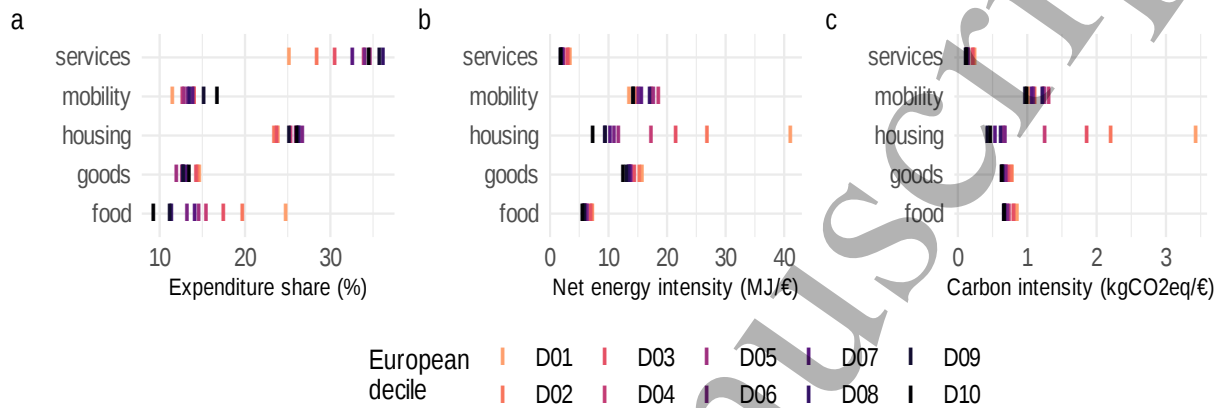

203

204 **Figure 1: Household final demand expenditure and environmental**
 205 **footprints and intensities across European expenditure deciles. Total**
 206 **expenditures (a), net energy footprint (composed of final energy**
 207 **footprint and losses) (b), and carbon footprint (c) per decile. Energy**
 208 **intensity of consumption as net energy footprint per expenditure (d),**
 209 **carbon intensity of consumption as carbon footprint per expenditure**
 210 **(e), and carbon intensity of energy as carbon footprint per net**
 211 **energy footprint (f).**

212 The different intensities of household consumption across European
 213 expenditure deciles can be attributed to a combination of two plausible
 214 causes: first, the composition of consumption baskets could systematically
 215 differ according to the level of household expenditure (20). Second, the
 216 energy and carbon intensity within individual final consumption categories
 217 could systematically differ across expenditure levels. Single country studies
 218 cannot usually capture this variation because, due to the homogeneous
 219 product assumption of input-output models, the national sectoral energy
 220 and carbon intensities are uniform. However, since household purchasing
 221 power is distributed very unequally across European countries, many

222 Eastern European households, for example, end up in the lower expenditure
 223 deciles and Scandinavian households tend to be in the higher ones (see SI,
 224 Figure S1). This allows us to capture part of the variance in energy and
 225 carbon intensities across European expenditure deciles (Figure 2).

226

227 **Figure 2: Final consumption category household expenditure shares**
 228 **(a) and environmental intensities (b and c) of European expenditure**
 229 **deciles.**

230 In this regard, the housing sector stands out with a carbon intensity of
 231 consumption more than 6 times higher in the bottom decile (3.4 kgCO₂eq/€)
 232 than in the top decile (0.5 kgCO₂eq/€). Housing had the highest variance in
 233 energy and carbon intensity among expenditure deciles, and for the bottom
 234 deciles, it was the most energy and carbon intensive category. Overall, with
 235 increasing expenditure decile, the shares of mobility and services increased
 236 and the shares of food and goods decreased. Households in the top decile
 237 spent about 35% on services, which had the lowest energy and carbon
 238 intensities of all final consumption categories, compared to 25% in the
 239 bottom decile.

240 The tendency for energy and carbon intensity to decrease with increasing
 241 affluence has been reported at the global level between countries (21–24)
 242 and also within Europe (19,25,26). In many countries of Eastern Europe,
 243 more than 80% of households are in the bottom four expenditure deciles,
 244 while in many high-income countries the figure is less than 20% (see SI,
 245 Figure S1).

246 The high intensities in the bottom four European expenditure deciles can be
 247 attributed in large part to more inefficient and dirtier domestic energy
 248 supply and demand technologies for heating and electricity generation in
 249 Poland, Bulgaria, the Czech Republic, and Romania. Poland alone was
 250 responsible for about 40% of total coal combustion for heat production in
 251 Europe in 2015 (27), and had a higher average intensity of carbon per MJ of
 252 heat delivered than both Europe and the world (28). We did not account for

253 energy subsidies here, but different subsidy levels in different countries
 254 could also influence energy and carbon intensities (29).

255 Inequality across final consumption categories

256 The five final consumption categories, housing, mobility, food, goods, and
 257 services, contributed very differently to the environmental footprint of
 258 European households in 2015 (Figure 3). On average, housing and mobility
 259 were the two largest categories, accounting for about two thirds of both the
 260 energy and carbon footprints. In addition, the sectoral footprint variation
 261 across the expenditure deciles was also high (Figure 3). For housing there
 262 was very little systematic difference between deciles in both the energy and
 263 the carbon footprint. The bottom four deciles even had higher carbon
 264 footprints from housing than most top deciles, which can be explained by
 265 the extreme differences in intensity shown in Figure 2. Mobility was the
 266 most unequal category, with footprints in the top decile 10 times higher
 267 than the bottom decile, corroborating findings in (10) and (9). Goods was
 268 the second most unequal final consumption category (90:10 ratios of 5.5 for
 269 energy, 5.4 for carbon), similar to services (90:10 ratios of 5.4 for energy
 270 and 4.9 for carbon) and then food (90:10 ratios of around 2 for both
 271 footprints).

272

273 **Figure 3: Household net energy and carbon footprints by final**
 274 **consumption category and European expenditure decile in 2015,**
 275 **further broken down by source and location. 'Direct' (direct energy**
 276 **use and carbon emissions from households) plus 'Domestic' (energy**

277 ***use and carbon emissions along the domestic national supply chain)***
278 ***make up that part of the household footprint coming from within***
279 ***national borders, while 'Europe' is the part from other countries***
280 ***within the sample (plus Italy and Luxembourg), and 'non-Europe'***
281 ***from all other countries.***

282 The geographical source of the energy and carbon footprints also varies by
283 consumption category (Figure 3). The housing footprint was almost entirely
284 domestic, with the direct environmental footprint for heating and cooling
285 accounting for 20% for net energy use and 24% for carbon emissions, and
286 the rest embedded primarily along the domestic supply chain. The mobility
287 footprint, on the other hand, was around one fourth non-European. The
288 majority of the mobility footprint came from vehicle fuel, either directly
289 from households, or indirectly, i.e. embedded along the supply chain. The
290 goods footprint was mostly non-European, while services and food were
291 both around one third non-European. These results suggest that proposed
292 future carbon border-adjustment mechanisms (11) will especially impact the
293 mobility and goods footprints of the higher deciles, and to a lesser extent
294 the food and services footprints.

295 **A 1.5°C compatible Europe**

296 Global 1.5°C compatible decarbonisation scenarios achieve a similar climate
297 outcome with different assumptions about the transformation of energy
298 supply and demand, from renewable capacity, and deployment of carbon-
299 capture-and-storage (CCS), to socio-technological demand transformation.
300 Table 1 shows some final energy values for the year 2050 from seven
301 different decarbonisation scenarios, already converted from total GJ/capita
302 to household GJ/adult equivalent. The original total GJ/capita scenario
303 values are for different world regions (OECD, West EU, Global North, and
304 Global), depending on the regional disaggregation of the scenarios, and so
305 should not be interpreted as perfectly comparable with each other. For the
306 purposes of our study, however, we are simply interested in the range of
307 scenario values within which to situate our household environmental
308 footprint results, presented below in the 'Inequality in a 1.5°C compatible
309 Europe' section and in Figure 5.

Table 1: Decarbonisation scenarios. Scenario: Shared Socioeconomic Pathways (SSP) 1-1.9, 2-1.9, and 2-2.6 (2°C scenario) (1), IEA Energy Technology Perspectives Beyond 2 Degrees (IEA ETP B2DS) (2), Global Energy Assessment (GEA)-efficiency (18), Low Energy Demand (LED) (2), Decent Living Energy (DLE) (4). Type: distinction between supply-side and demand-side scenarios. GEA-efficiency categorized as a 'mix' due to some bottom-up quantifications of final energy demand in some sectors. Final energy in 2050: final energy estimates for 2050 per scenario, converted from total GJ/capita to household GJ/adult equivalent. The original total GJ/capita values are for different world regions (OECD, West EU, Global North, and Global), depending on the regional disaggregation of the scenarios.

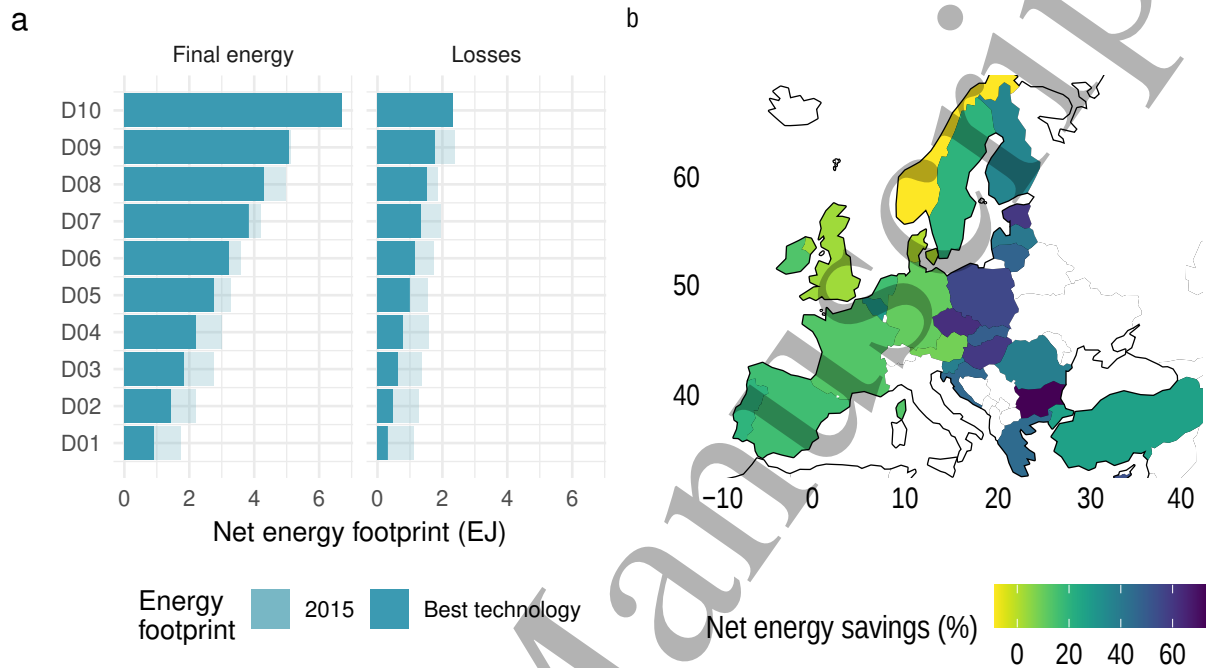

Scenario	Type	Final energy in 2050: household GJ/adult equivalent
SSP2-2.6	supply-side	119
SSP2-1.9	supply-side	98
SSP1-1.9	supply-side	90
IEA ETP B2DS	supply-side	87
GEA-efficiency	mix	66
LED North	demand-side	55
LED global	demand-side	28
DLE	demand-side	16

The various global supply-side 1.5°C scenarios (SSP1-1.9, SSP2-1.9, GEA-efficiency, IEA ETP B2DS) (1,2,18) would see the European household final energy footprint falling from the 2015 level of 38 EJ to around 22-33 EJ by 2050, equivalent to a per adult equivalent reduction from a 2015 average of 112 GJ (final energy) to around 66-98 GJ. The differences in final energy in 2050 in the scenarios reflect different model assumptions about the rate of expansion of renewable energy, efficiency improvements and conservation, and CCS capacity. All these scenarios rely on CCS, which is still a fairly speculative technology, and we therefore interpret them as ranges for the upper limits of 1.5°C compatible energy supply (1,18).

1
2
3 332 It is more difficult to determine a lower limit for the minimum amount of
4 333 energy use required for a decent standard of living. Such a lower limit
5 334 depends strongly on the prevalent socio-cultural idea of what constitutes a
6 335 decent life, and, perhaps even more strongly, on the physical infrastructure
7 336 available to deliver this. The two global demand-side scenarios, Low Energy
8 337 Demand (LED) (2) and Decent Living Energy (DLE) (4), that attempt to
9 338 define such a limit conclude that, in principle, a very low household final
10 339 energy use, between around 16-55 GJ/ae could be sufficient. However, these
11 340 scenarios rely on socio-technological transformations on a scale that,
12 341 especially at the lower end, far exceed the current political discourse on the
13 342 subject. Both scenarios are 1.5°C compatible without resorting to any CCS
14 343 but they implicitly (LED) (2) or explicitly (DLE) (4) assume near full equality
15 344 of consumption across the population. To put these low energy numbers in
16 345 perspective, the average household final energy footprint in our sample was
17 346 112 GJ per adult equivalent in 2015. The high estimate in the LED scenario
18 347 is about the same as the final energy footprint of the bottom European
19 348 expenditure decile (52 GJ/ae).

20
21
22
23
24 349 Based on these two constraints, the upper limit on the supply side and the
25 350 lower limit on the demand side, it is possible to make a generalized estimate
26 351 of how much inequality in the distribution of energy use is numerically
27 352 possible, if at the same time global warming is to be kept below 1.5°C and a
28 353 decent standard of living for all is to be made possible. Before we can make
29 354 this evaluation, we must take into account the existing large differences in
30 355 the technological efficiency of energy supply and use (Figure 2).

356 **Counterfactual: empirical best technology per final**
 357 **consumption category**

358
 359 **Figure 4: Energy savings if all deciles used the best technology per**
 360 **final consumption category available in 2015: by a) expenditure**
 361 **decile and b) country.**

362 Our results show that in 2015, higher-income households in higher-income
 363 countries had access to the most energy-efficient energy services across the
 364 final consumption categories (Figure 2). Since we are interested in the
 365 largest numerically possible inequality in the distribution of energy
 366 footprints from actual household consumption, we calculated a
 367 counterfactual in which all European deciles use the best technology
 368 available in 2015 (Figure 4).

369 Around 11 EJ net energy would have been saved in total in 2015, if all
 370 deciles had the same energy intensity per final consumption category as the
 371 top decile (5.3 EJ from final energy and 5.7 EJ from avoided losses). The
 372 average net energy footprint would have been 131 GJ/ae instead of 164
 373 GJ/ae, and the net energy footprint of the bottom decile would have been
 374 less than half (-57%) its 2015 value (Figure 4a) with a 47% reduction in final
 375 energy use and 72% fewer conversion losses. The saved energy would have
 376 been especially large in Eastern Europe, over 60% for Bulgaria and the
 377 Czech Republic for example (Figure 4b). Poland would have saved the most
 378 in absolute terms, at 1.8 EJ. Energy inequality would have been higher, at a
 379 90:10 ratio of 7.3 (for both net and final energy; close to expenditure

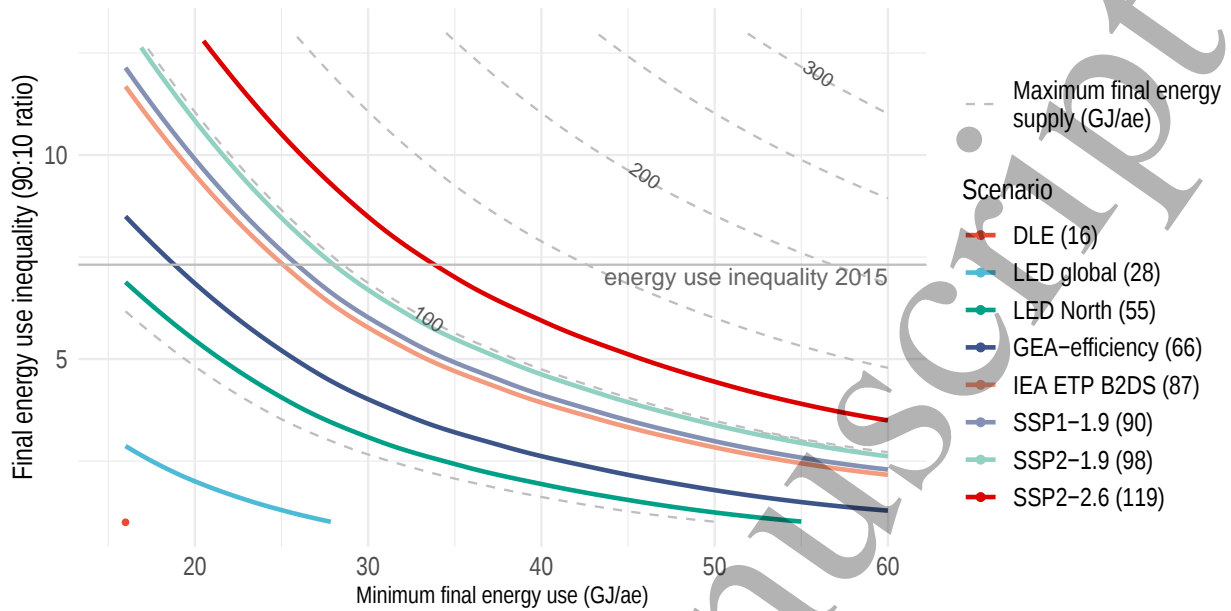

1
2
3 380 inequality, at 7.2, as the differences in intensity per decile are removed but
4 381 differences in the consumption baskets remain), compared to our actual
5 382 2015 energy inequality estimate of a 90:10 ratio of 3.1 (net energy; 3.9 for
6 383 final energy).

8 9 384 **Inequality in a 1.5°C compatible Europe**

10
11 385 Based on this counterfactual distribution of the energy footprint using
12 386 homogeneous technologies, we scaled down the final energy footprint
13 387 across European expenditure deciles to meet supply constraints on average
14 388 and, where necessary, adjusted the distribution to not undershoot minimum
15 389 energy use in any decile (Figure 5).

16
17 390 Both the DLE and LED scenarios satisfy final energy demand for a decent
18 391 standard of living and are compatible with the 1.5°C target without
19 392 resorting to CCS technologies (2,4). The DLE scenario explicitly envisions
20 393 absolute global equality (a 90:10 ratio of 1) in energy consumption, except
21 394 for small differences in required energy consumption based on climatic and
22 395 demographic factors, as well as differences in population density (4). The
23 396 LED scenario does not explicitly discuss distributional aspects beyond
24 397 giving different final energy values for the Global North (around 55
25 398 household GJ/ae) and the Global South (around 21 household GJ/ae) (2).
26 399 However, due to the bottom-up construction of these demand scenarios,
27 400 these values can be interpreted as estimates for available final energy
28 401 supply. The energy supply scenarios do not include specific details about
29 402 how the energy footprints are distributed within countries (1,30). They
30 403 achieve energy savings through the replacement of carbon-intensive fossil
31 404 fuels by cleaner alternatives, efficiency improvements including the
32 405 electrification of final energy, and some measures towards energy
33 406 conservation (1).

408 **Figure 5: The maximum available average final energy supply**
 409 **(colored scenario lines and dashed elevation lines, in household**
 410 **GJ/adult equivalent) in the 1.5°C compatible scenarios, and for**
 411 **comparison one 2°C scenario (SSP2-2.6), together with the assumed**
 412 **minimum final energy use (household GJ/adult equivalent) for a**
 413 **decent life, determine the maximum level of final energy use**
 414 **inequality (expressed as 90:10 top-to-bottom decile ratio) while**
 415 **achieving both goals. Energy inequality was calculated for**
 416 **harmonized best technology per final consumption category.**

417 The colored curves in Figure 5 represent constant average household final
 418 energy footprints according to the different scenarios. The slopes of the
 419 curves connect different assumptions about minimum final energy use for a
 420 decent life (on the x-axis) with the corresponding maximum final energy
 421 inequality that is consistent with the available final energy supply. The
 422 figure shows that at the 2015 inequality level, even the 1.5°C scenarios with
 423 high CCS deployment (SSP2-1.9, SSP1-1.9, IEA ETP B2DS) can only be
 424 achieved with extremely low minimum energy use assumptions (about 28
 425 GJ/ae (LED, global average)). To achieve these scenarios with the still
 426 ambitious but much more realistic 55 GJ/ae (LED, Global North), the 90:10
 427 ratio would need to be reduced by about two-thirds. The GEA-efficiency
 428 scenario would allow almost no inequality at this minimum energy use, and
 429 to achieve the SSP2-2.6 scenario, the 90:10 ratio would still need to be cut
 430 by about half.

ACCEPTED

431 Conclusions

432 Our empirical results show that the most obvious and urgent challenge is
433 that the carbon and energy intensities of the poorest households, especially
434 in Eastern Europe, must converge with those in the top expenditure deciles.
435 In practice, this corresponds to the need for large-scale investments in the
436 technical efficiency of heat, electricity and hot water supply and use (25).
437 New and existing transition funds for lower-income countries need to be
438 targeted, and at an appropriately large scale, to reduce the high intensities
439 of consumption in the lower deciles (11,31). Improving technical efficiency
440 is already a major part of EU policy. However, according to EUROSTAT, a
441 majority of households in the lowest decile experience severe material
442 deprivation (32), suggesting that their energy use would need to be
443 increased to ensure a decent standard of living unless efficiency can be
444 improved even further.

445 Even under the bold assumption that the energy and emission efficiencies of
446 all expenditure deciles converge, and demand develops as in the 1.5°C
447 scenarios, our results show that a drastic reduction in the inequality of
448 energy footprints can only be avoided if either massive negative emissions
449 or very low minimum final energy use for decent living standards are
450 assumed, both of which present immense challenges.

451 The practical feasibility of achieving the necessary pace and scale of CCS
452 deployment is highly contested. Actual deployment over the past 10 years
453 has been very slow, with only 20 large scale facilities in operation in 2020,
454 capturing in total only 40 million tons of CO₂ (33). To mitigate CO₂
455 emissions on the order of the 1.5°C-2°C scenarios with heavier CCS
456 deployment, it has been estimated that the CCS industry would need to be
457 more than twice the size of the current global oil industry in terms of
458 volume by 2050 (34). High costs, safety and environmental concerns are
459 further barriers to a rapid deployment of CCS (35-37).

460 Ensuring a decent standard of living for all at the targeted minimum final
461 energy level of the demand-side scenarios (between around 16 to 55
462 household GJ per adult equivalent (2,4), down from an average of 112
463 household GJ/ae) requires a fundamental reorganization of almost all areas
464 of life and economy. It seems hard to imagine how, for example, the living
465 space per capita can be reduced from about 40m² to 30m² (LED) (2), let
466 alone to 15m² (DLE) (4), or that air travel can be capped at one short-to-
467 medium-haul return flight every three years per person, which is an
468 assumption behind the DLE scenario (4).

469 The key finding of our study, however, is that any increase in minimum
470 energy use for a decent life, like any reduction in available energy supply,
471 inevitably increases the need to redistribute the energy footprint across
472 countries and expenditure groups, i.e. to reduce the energy use of the

1
2
3 473 higher expenditure deciles ever more drastically. Achieving this seems at
4 474 least as difficult politically. The idea of capping the energy use of higher-
5 475 income households plays virtually no role in current climate and energy
6 476 policy. Our results show that such strategies will be inevitable, unless very
7 477 low minimum energy use of 28 GJ/ae plus heavy deployment of CCS are
8 478 realized. Realistically, in addition to measures to reduce average
9 479 environmental footprints, further instruments to reduce inequality in energy
10 480 use and intensity must be developed to ensure a just transition that “leaves
11 481 no one behind,” as promised by the European Green Deal (11).

12
13
14 482 Particularly in the coming phase of necessary restructuring of the European
15 483 economy, a social protection mechanism of whatever kind assuring a decent
16 484 life will play a central role. However, the current institutions of Europe, and
17 485 the eurozone in particular, offer their member states, especially the less
18 486 prosperous ones where the challenges of a green transformation are
19 487 greatest, little monetary or fiscal leeway to strengthen or introduce such
20 488 measures. In the eurozone, implementation fails due to the lack of a
21 489 common economic policy, as well as the fact that the European Central
22 490 Bank (ECB) (unlike other central banks) only has a mandate to stabilize
23 491 prices, but not to provide full employment or other effective means of social
24 492 protection for European citizens (38). In general there is a great need for
25 493 action to increase the scope for national and/or EU-wide policy making;
26 494 both to ensure the social protection of citizens and to enable the necessary
27 495 investments to restructure infrastructure and the economy (39).

28
29
30
31 496 Strong carbon pricing and progressive compensation schemes could have a
32 497 positive distributional effect besides the effect on absolute emission
33 498 reduction (40,41). In addition, other distribution and transfer instruments
34 499 (42), such as wealth and inheritance taxes, or more progressive
35 500 expenditure, consumption and income taxes (43), will have to be discussed
36 501 in order to reduce the large differences in purchasing power within and
37 502 between the countries of Europe, at least as long as expenditure remains
38 503 coupled to environmental footprints (44).

39
40
41 504 Our study highlights the challenges largely implicit in the 1.5°C scenarios
42 505 with respect to securing a decent standard of living for all, and provides
43 506 further evidence that achieving this dual objective likely requires a shift in
44 507 the current policy focus on growth in favor of decreasing environmental
45 508 impacts and increasing social equity (44,45). Although our empirical
46 509 investigation is limited to countries in Europe, we contend that our main
47 510 conclusions apply in a similar or stronger form to the global achievement of
48 511 climate and equity goals, as articulated in the sustainable development
49 512 goals.
