Abstract:

Much of our understanding of Earth’s past climate comes from the measurement of oxygen and carbon isotope variations in deep-sea benthic foraminifera. Yet, long intervals in existing records lack the temporal resolution and age control needed to thoroughly categorize climate states of the Cenozoic Era and to study their dynamics. Here we present a new, highly resolved, astronomically dated, continuous composite of benthic foraminifer isotope records developed in our laboratories. Four climate states – Hothouse, Warmhouse, Coolhouse, Icehouse – are identified based on their distinctive response to astronomical forcing depending on greenhouse gas levels and polar ice sheet volume. Statistical analysis of the non-linear behavior encoded in our record reveals the key role that polar ice volume plays in the predictability of Cenozoic climate dynamics.

One Sentence Summary:

During the last 66 million years Earth’s climate system response to astronomical forcing was state-dependent.
Global changes in Earth’s climate during the Cenozoic Era, the last 66 million years, have long been inferred from stable isotope data in carbonate shells of benthic foraminifers, which are single-celled amoeboid organisms that live on the seafloor. Carbon and oxygen isotope records from deep-sea benthic foraminifers are a proven, invaluable archive of long-term changes in Earth’s carbon cycle, deep-sea temperature, and seawater composition driven by changes in ice volume (1, 2). In 1975, Shackleton and Kennett (3) produced one of the first deep-sea benthic foraminifer stable isotope records of the Cenozoic. Despite being of low temporal resolution it revealed that Earth’s climate had transitioned from a warm state 60 to 40 million years ago (Ma) to a cool state 10 to 5 Ma. Over the last 45 years, many deep-sea benthic foraminifer stable isotope records of variable length and quality have been developed, resulting in a more detailed record of Cenozoic climate change. Compilations of these deep-sea isotope records provide a compelling chronicle of past trends, cyclic variations, and transient events in the climate system from the Late Cretaceous to today (1, 4-10). However, even the most recent benthic isotope compilations cannot accurately document the full range and detailed characteristics of Cenozoic climate variability on time scales of ten thousand to one million years. Age models and temporal resolution of Cenozoic benthic isotope compilations are either too coarse and/or include gaps, particularly prior to 34 Ma. These weaknesses hamper progress in determining the dynamics of the Cenozoic climate system (4, 9, 11), for example, because they prohibit application of advanced techniques of non-linear time series analysis at the required (astronomical) time-scales. The lack of highly-resolved, continuous, and accurately dated records constitutes a key limitation in our ability to identify and understand the characteristics of Earth’s evolving climate during the Cenozoic.
Here, we present a new astronomically tuned deep-sea benthic foraminifer carbon $\delta^{13}C$ and oxygen $\delta^{18}O$ isotope reference record uniformly covering the entire Cenozoic, developed in our laboratories using sediment archives retrieved by scientific ocean drilling (Fig. 1). To produce this new composite record, we selected 14 ocean drilling records, checked and revised their composite splices where necessary, and preferentially selected records utilizing the genus *Cibicidoides* and *Nuttallides* to minimize systematic interspecies isotopic offsets (1, 4, 12, 13). We additionally generated new benthic stable isotope data spanning the late Miocene and middle-to-late Eocene to fill intervals inadequately covered by existing records. We collated existing astrochronologies for all records, recalibrated them to the La2010b orbital solution (14) if required, and developed a new astrochronology for the middle-to-late Eocene (13). We estimate our chronology to be accurate to ± 100-kyr for the Paleocene and Eocene, ± 50-kyr for the Oligocene to middle Miocene, and ± 10-kyr for the late Miocene to Pleistocene. The composite record is affected by some spatial bias arising from the uneven distribution of deep-sea stable isotope data that mainly derive from low- to mid-latitudes (13). Nevertheless, the resulting new Cenozoic Global Reference benthic foraminifer carbon and oxygen Isotope Dataset (CENOGRID) provides a refined record with higher signal-to-noise ratio than any previous compilations ((13); text S1), and better coverage of the Paleocene, Eocene and late Miocene intervals (Fig. S32). The CENOGRID serves as an astronomically tuned high-definition stratigraphic reference of past global climate evolution for the past 66 million years.

On time scales of ten thousand to one million years, global climate is a complex, dynamical system responding non-linearly to quasi-periodic astronomical forcing. By combining the latest high-resolution generation of Cenozoic deep-sea isotope records on a highly accurate timescale, CENOGRID enables the definition of Earth’s fundamental climates and investigation of the
predictability of their dynamics. We used recurrence analysis (RA) of the CENOGRID record
\((13, 15)\) to identify fundamental climate states that internally share characteristic and statistically
distinctive dynamics. Recurrence is a major property of dynamical systems and RA provides
information about non-linear dynamics, dynamical transitions, and even non-linear
interrelationships \((15)\), and facilitates evaluation of underlying dynamical processes – e.g.,
whether they are stochastic, regular, or chaotic. We present recurrence plots and their
quantification of the benthic foraminifer \(\delta^{13}\text{C}\) and \(\delta^{18}\text{O}\) records to recognize different climate
states and apply the RA measure of ‘determinism’ (DET) to quantify the predictability of
Cenozoic climate dynamics.

Four distinctive climate states emerge as distinct blocks from our recurrence plots of the \(\delta^{18}\text{O}\)
CENOGRID record that we label Hothouse, Warmhouse, Coolhouse, and Icehouse state (Fig. 2).
Block-like structures in the recurrence plots identify epochs where the dynamical system is
‘trapped’ in a particular state. This interpretation of Cenozoic climate history is broadly
consistent with previous interpretations but our recurrence plot analysis of the highly resolved
CENOGRID data provides a more statistically robust and objective exposition of events.

Detailed features of the four climate states can be inferred from the isotope profiles (Fig. 1) and
scatter plots of the CENOGRID \(\delta^{13}\text{C}\) and \(\delta^{18}\text{O}\) data, and atmospheric \(\text{CO}_2\) concentration
estimates (Fig. 2; \((13)\)). Warmhouse and Hothouse states prevailed from the
Cretaceous/Paleogene boundary (K/Pg, 66 Ma) to the Eocene-Oligocene Transition (EOT, 34
Ma). During the Warmhouse, global temperatures were more than 5°C warmer than today \((13)\)
and benthic \(\delta^{13}\text{C}\) and \(\delta^{18}\text{O}\) show a persistent positive correlation with one another. The Hothouse
operated between the Paleocene-Eocene Thermal Maximum at 56 Ma and the end of the Early
Eocene Climate Optimum (EECO) at 47 Ma \((16)\), when temperatures were more than 10°C
warmer than today and displayed greater amplitude variability. Transient warming events (hyperthermals) are an intrinsic feature of the Hothouse, wherein paired negative excursions in \( \delta^{13}\text{C} \) and \( \delta^{18}\text{O} \) reflect warming globally through rapid addition of carbon to the ocean-atmosphere system. The two Warmhouse phases from 66 to 56 Ma (Paleocene) and 47 to 34 Ma (middle-late Eocene) share a similar temperature range but have distinct background \( \delta^{13}\text{C} \) isotope values and atmospheric \( \text{CO}_2 \) levels (Fig. 2, S35). At the EOT, the Warmhouse transitioned into the Coolhouse state, marked by a stepwise, significant drop in temperature and a major increase in continental ice volume with large ice-sheets appearing on Antarctica (17) to establish a unipolar glacial state (18). The recurrence plots mark out the EOT as the most prominent transition of the whole Cenozoic, which highlights the important role of ice sheets in modulating Earth’s climate state (Fig. S33; (13)).

The Coolhouse state spans ~34 Ma (EOT) to 3.3 Ma (mid Pliocene M2 glacial), and is divided into two phases by the marked shift in \( \delta^{18}\text{O} \) increase at 13.9 Ma related to the expansion of Antarctic ice sheets during the middle Miocene Climate Transition (mMCT; (19)). Warmer conditions culminating in the Miocene Climatic Optimum (MCO; ~17-14 Ma; (20)) characterize the first phase, followed by cooling and increasing \( \delta^{18}\text{O} \) during the second phase (Fig 2). RA of carbon isotope data documents an additional major transition in the carbon cycle around 7 Ma related to end of the late Miocene Carbon Isotope Shift (11, 21, 22). A major change in the correlation between benthic foraminifer \( \delta^{13}\text{C} \) and \( \delta^{18}\text{O} \) occurs during the Pliocene epoch (23).

The Icehouse climate state (Fig. 2), driven by the appearance of waxing and waning ice sheets in the northern hemisphere, was fully established by the Pliocene-Pleistocene transition (24) (Fig. 1, 2) with Marine Isotope Stage M2 at 3.3 Ma being a possible harbinger. The recurrence plots are less pronounced and more transparent from 3.3 Ma to today (Fig. 2, S34), suggesting that
Earth’s climate-cryosphere dynamics entered a state not comparable to anything seen in the preceding 60 or more million years.

The CENOGRID allows us to scrutinize the state-dependency of climate system response to CO$_2$ and astronomical forcing on ten thousand to one million year time scales (13). Astronomical forcing throughout the Cenozoic is consistently uniform, but the RA indicates that the non-linear response in climate variability to this forcing is strongly influenced by the fundamental state of climate. Evolutionary spectrograms characterize the dominant climatic response to astronomical forcing during the Cenozoic (Fig. 3). We find that the prevailing climate state as characterized by atmospheric CO$_2$ concentration and polar ice sheets seems to orchestrate the response and impact of climate processes to astronomical forcing. Modeled insolation-driven global temperature variability on astronomical time scales suggest that different temperature response regimes exist: eccentricity dominates temperature responses in low latitudes, precession in mid latitudes and obliquity in high latitudes (25). Thus, pronounced astronomical cyclicity in the CENOGRID could reflect climate-state dependent amplifications of latitude-specific climate processes.

In the Hothouse and Warmhouse, as well as the first Coolhouse phase, eccentricity-related cycles dominate the CENOGRID indicating a strong influence of low-latitude processes on climate variations. Obliquity-related cycles are sparse in these intervals, but have been documented in other geochemical records (26, 27) exhibiting perhaps local lithological responses. Weak response in the obliquity-band during the Hothouse and Warmhouse intervals might be related to the absence of a high-latitude ice sheet that could have amplified climate response to obliquity forcing. The driving mechanism for the prevailing eccentricity cyclicity in the benthic $\delta^{13}$C and $\delta^{18}$O records is still unknown, but modeling suggests that low- and mid-latitude processes in the climate system respond in a non-linear way to insolation forcing (25, 28-30). In this regard, a key
feedback likely involves the hydrological cycle with highly seasonal precipitation patterns during intervals of strong monsoon response to precession-induced insolation change which could play a major role in the global distribution of moisture and energy (31-34). The expression of precession is apparently weak in the CENOGRID composite record despite the dominant eccentricity forcing, likely due to the long residence time of carbon in the oceans enhancing longer forcing periods (30, 35), as well as our strategy to avoid ‘overtuning’ the record. Following the increasing influence of high latitude cooling and ice growth during the second Coolhouse phase, the obliquity-band response steadily increases after the mMCT before dominating climate dynamics by the late Miocene-early Pliocene (11, 22, 36). In the Icehouse state, the progressive decrease in atmospheric CO2 and major growth of polar ice sheets, which enhanced variability in δ18O, steadily amplified the influence of complex high latitude feedbacks until they essentially dominate climate dynamics.

To better understand the complexity of climate dynamics recorded in the CENOGRID, we computed the RA measure of determinism (DET, (13)). This parameter quantifies the predictability of dynamics in a system's state. Predictability estimates the stochastic (unpredictable) versus the deterministic (predictable) nature of climate dynamics recorded in CENOGRID (13). DET values near zero correspond to unpredictable dynamics, whereas large values indicate predictable dynamics, which are especially interesting to examine on the approach to tipping points. Changes in DET can thus reveal transitions between fundamentally different climate regimes.

Our RA suggests that climate dynamics during the Warmhouse and Hothouse Cenozoic states are more predictable or more regular than those of the Coolhouse and Icehouse states (Fig. 3). The growth of polar ice sheets at the EOT enhanced the effect of obliquity pacing of high
latitude climate that interacted with eccentricity-modulated precession forcing at lower latitudes from that point in time. This led to increased non-linear interactions among astronomically paced climate processes, and thus more complex, stochastic climate dynamics. The development of large Antarctic ice volume at the inception of the Coolhouse is associated with a fundamental regime change towards less predictable climate variability (lower DET values calculated from benthic δ18O, Fig. 3). From 25 to 13.9 Ma DET is elevated again, related to a reduction in ice volume in relatively warmer times of the Coolhouse, culminating in the MCO. Despite the growing influence of ice sheets in the Coolhouse, until ~6 to 7 Ma carbon cycle dynamics remain more deterministic than temperature because δ13C variations are predominantly driven by low-latitude processes and less strongly influenced by the complex interaction with polar ice-sheet fluctuations. After ~6 Ma DET drops likely due to stronger cryosphere imprint on the carbon cycle. Upon initiation of the Icehouse at 3.3 Ma, δ18O recorded climate dynamics become slightly more deterministic (37) and carbon cycle dynamics unpredictable, likely resulting from the complex response to the waxing and waning of polar caps (38).

The CENOGRID spectrogram displays a broader frequency range during several intervals with low DET values (e.g., Coolhouse), while high DET values (e.g., Warmhouse) occur when single frequencies dominate (Fig. 3). This could be signaling a more direct response to astronomical forcing in the Warmhouse compared to the Coolhouse. Our RA suggests that the Hothouse is more stochastic (less predictable) than the Warmhouse, presumably induced by the occurrence of extreme hyperthermal events and their strong non-linear and much amplified climate response to astronomical forcing (39, 40). The evolving pattern in the DET from the onset of cooling after the EECO to the EOT is striking (Fig. 3). The amplitude in fluctuations between stochastic and deterministic dynamics intensifies from 49 Ma to 34 Ma, consistent with how Earth’s climate
system is suggested to behave \((41, 42)\) as it moves towards a major tipping point. Once that tipping point is reached at the EOT, a rapid shift toward more permanently stochastic dynamics marks the inception of a new climate state \((43)\). Thus polar ice volume is not only critical to defining Earth’s fundamental climate state, it also seems to play a critical role in determining the predictability of its climatological response to astronomical forcing.

References (45-181)
Fig. 1. Cenozoic Global Reference benthic carbon and oxygen Isotope Dataset (CENOGRID) from ocean drilling core sites spanning the past 66 million years. Data are mostly generated using benthic foraminifera tests of the taxa *Cibicidoides* and *Nuttalides* extracted from carbonate rich deep-sea sediments drilled during ODP / IODP expeditions. Genus-specific corrections were applied and oxygen isotope data adjusted by +0.64‰ and +0.4‰, respectively (12), with the green dot indicating the average oxygen isotope composition of the last 10 kyr. Average resolution for the last 34 million years is one sample every 2 kyr, for the interval from 34 to 67 million years 4.4 kyr. After binning data were resampled and smoothed by a locally weighted function over 20 kyr (blue curve) and 1 Myr (red curve) to accentuate the different rhythms and trends in Earth’s carbon cycle and temperature operating on various time scales. Oxygen isotope data have been converted to average temperature differences with respect to today (13). Future projections for global temperature (44) in the Year 2300 are shown by plotting three Representative Concentration Pathways (RCP) scenarios are plotted (light and dark blue, red dots). Gray horizontal bars mark rough estimates of ice volume in each hemisphere. Absolute ages for epochs and stages of the Cenozoic (GTS2012) and geomagnetic field reversals (this study) are provided for reference. Note that the oxygen isotope data axis is reversed to reflect warmer temperatures at times of lower δ18O values. K/Pg is the Cretaceous/Paleogene boundary, Oi-1 is the first major glacial period in the Oligocene, M2 is the first major glacial event in the Northern Hemisphere.

Fig. 2. Climate states of the Cenozoic. Deep-sea benthic foraminifer high-resolution carbon (A) and oxygen (B) isotope records and the respective recurrence plots as well as scatter plots of long-term benthic foraminifer carbon versus oxygen values (C) and oxygen values versus atmospheric CO2 concentrations (D). Recurrence analysis compares climate change patterns occurring in a specific interval to the entire record. If climate dynamics have similar patterns they will show up as darker areas in the plot, if they have no common dynamics the plot will remain white. Four distinct climate states can be identified as Hothouse, Warmhouse, Coolhouse, and Icehouse with distinct transitions among them. The relation of oxygen isotopes, representative for average global temperature trends, to atmospheric CO2 concentrations suggests that the present climate system as of today (415 ppm CO2) is comparable to the Miocene Coolhouse close to the Miocene Climate Optimum. If CO2 emissions continue unmitigated until 2100 as assumed for the RCP8.5 scenario, the Earth climate system will be moved abruptly from the Icehouse into the Warmhouse or even Hothouse climate state.

Fig. 3. Quasi-periodic changes and determinism in the global reference carbon cycle and oxygen isotope record. Evolutionary FFT spectrogram, recurrence determinism analysis and benthic foraminifer oxygen (A) and carbon (B) isotope data plotted on age with the four climate states. Frequencies between two and sixty cycles per million years are related to changes in Earth’s orbital parameters, known as Milankovitch cycles. The FFT spectrograms were computed with a 5-Myr window on the detrended records of benthic carbon and oxygen isotope data. From 67 to 13.9 Ma cyclic variations in global climate are dominated by the 405- and 100-kyr eccentricity cycles. Thereafter, in particular in the oxygen isotope record, the influence of obliquity increased, dominating the rhythm of climate in the record younger than ~7.7 million years. Recurrence analysis of determinism (DET) shows that climate in the Warmhouse state is more deterministic (predictable) than in the Hot-, Cool- and Icehouse. From 47 Ma towards the Eocene-Oligocene Transition at 34 Ma climate dynamic changes are rising in amplitude.
approaching a threshold in the Climate System. If DET tends to low values, the dynamics are stochastic, whereas high values represent deterministic dynamics.

Materials and Methods

1. New Stable Carbon and Oxygen Isotope Data

New high-resolution stable carbon and oxygen isotope data were generated on bulk carbonate and deep-sea benthic foraminifer carbonate from key intervals to assure full coverage of the Cenozoic. Here we describe the methods used to collect new data from biogenic carbonates at Sites 1263, 1264, and 1265. Ocean Drilling Program (ODP) Leg 208 Sites 1263 (28°32'S, 2°47'E), 1264 (28°32'S, 2°51'E), and 1265 (28°50'S, 2°38'E) drilled during Ocean Drilling Program (ODP) Leg 208 are located on the Walvis Ridge in the SE Atlantic (45) in 2,717 m, 2,505 m, and 3,059 m water depth (Fig. S1).

Bulk carbonate δ¹³C and δ¹⁸O analyses on 2000 freeze-dried and pulverized sediment samples from Site 1263 (80.69 to 156.40 rmcd depth) spanning the period from 32 to 41.7 Ma were undertaken at MARUM, University Bremen to validate and improve the benthic record. The bulk stable carbon and oxygen isotope data from the MARUM lab are reported relative to the Vienna Pee Dee Belemnite (VPDB) international standard, determined via adjustment to calibrated in-house standards and NBS-19. Bulk carbonate analyses at MARUM were carried out on Finnigan MAT 251 mass spectrometers equipped with automated carbonate preparation lines (Kiel I or III). Carbonate was reacted with orthophosphoric acid at 75 °C. Analytical precision based on replicate analyses of in-house standard (Solnhofen Limestone) is 0.03‰ (1σ) for δ¹³C and 0.05 - 0.07‰ (1σ) for δ¹⁸O.

Benthic foraminifer tests carbonate δ¹³C and δ¹⁸O were measured on 2934 samples at MARUM and University of Cambridge. At the MARUM lab, good to moderately preserved specimen of benthic foraminifera Nuttallides truempyi, Cibicidoides praemundulus, Oridorsalis umbonatus (Eocene) from the >150µm fraction, as well as Cibicidoides mundulus (C. kullenbergi) and Cibicidoides wuellerstorfi (Miocene-Pliocene) picked from the 250-500µm fraction were measured on samples from ODP Sites 1263 (1998 samples), 1264 (85 samples), and 1265 (217 samples). Each measurement was made using a single species. Analysis at MARUM were performed on Finnigan MAT 251 with Kiel III, Finnigan MAT 252 with Kiel III, or ThermoFisher Scientific 253plus with Kiel IV automated carbonate preparation line. Samples were reacted with orthophosphoric acid at 75 °C. Analytical precision based on replicate analyses of in-house standard (Solnhofener Limestone) averages 0.02 - 0.04‰ and 0.05 - 0.07‰ (1σ) for δ¹³C and δ¹⁸O, respectively. Data are reported relative to the Vienna Pee Dee Belemnite international standard, determined via adjustment to calibrated in-house standards and NBS-19.

At the University of Cambridge lab 634 20-cc samples taken every 2-3 cm from the composite section of ODP Site 1264 between 58 and 75 rmcd were processed. Oxygen and carbon isotope ratios were measured on the benthic foraminifer Cibicidoides wuellerstorfi and Cibicidoides mundulus from the >150 µm size fraction. Benthic foraminifer tests were cleaned in an ultrasonic bath to remove fine-grained particles and soaked in 15% H₂O₂ to remove surface organic contaminants prior to analysis. The number of specimens of C. wuellerstorfi/C. mundulus varied from 1 to 4. Each measurement was made using a single species. Benthic tests were crushed and between 20 and 60 µg of calcite were used for each analysis. The foraminifer calcite was reacted in orthophosphoric acid at 70°C using a Finnigan-MAT Kiel III carbonate preparation device. Evolved CO₂ gas was measured online with a Finnigan-MAT 252 mass spectrometer at the University of Florida. All isotope results are reported in standard delta notation relative to Vienna Pee Dee Belemnite (46). Analytical precision for both δ¹⁸O and δ¹³C was better than ±0.1‰.
All new stable carbon and oxygen isotope data are reported in the other supplementary materials Tab. S8 (Site 1263), Tab. S9 (Site 1264), Tab. S10 (Site 1265), Tab. S11 (Site 1263 bulk), and plotted against drilled depth in Fig. S2.

Our new bulk stable isotope data from ODP Site 1263 combined with the previously published data (47) compose to a 150-meter-long record with 3-5 kyr resolution covering the entire middle to late Eocene from 32 to 49 Ma (Fig. S2). The new benthic foraminifer data presented here span the period from 35.6 to 48.2 Ma. Together with the published data of the Late Lutetian Thermal Maximum (LLTM, (48)), latest Eocene (49) and the EOT (50), the Site 1263 benthic foraminifer record has an unprecedented average resolution of 5-7 kyr over the entire middle to late Eocene.

New benthic foraminifer stable isotope data were generated with samples from ODP Site 1264 (Fig. S2) to fill gaps in the record after revision of the late Miocene-Pliocene shipboard composite splice and extend the published 0 to 5.25 Ma record (51) back to 6.1 Ma. At ODP Site 1265 new benthic foraminifer data (Fig. S2) were generated between 38.0 and 39.4 Ma to test the revised composite record for Site 1263 (see below) as well as between 48.0 and 49.8 Ma to cover an interval of coring disturbance in Site 1263 (52).

2. Splice revision Site 1263

Deep-sea drilling techniques and methods have evolved and now allow to retrieve complete nearly undisturbed and successive 9.6-meter-long cores from the upper 200 to 400 meters of the soft sediment pile. Between the consecutively taken drill cores a recovery gap always exists, mostly due to ship motion (53). Common practice is to drill several offset, parallel holes at the same site, to then correlate all cores using physical properties data and core images (54) to generate a complete record from spliced intervals out of the parallel cores that represents the full sedimentary package targeted by drilling. The splicing of cores towards a composite heavily relies on the core and data quality used for correlation. The shipboard composite record of Site 1263 was already revised using shipboard magnetic susceptibility data and high-resolution digital line scan core images (W15 splice; (47)). Due to slight coring disturbance this revision revealed a difficult to splice interval around 125 rmcd between cores 1263B-6H, 1263B-7H, and 1263C-2H, which required a reevaluation by additional parameters, in this case stable isotope data.

Therefore, we generated high-resolution stable isotope data at on benthic foraminifer tests extracted from Cores 1263C-2H and 1263B-7H (Fig. S3) that reveal a mismatch in the overlapping interval between cores at 126 rmcd in the W15 splice (47). By moving Core 1263C-2H up by 50 cm, a reasonable match was found. To validate this correlation, we generated a benthic foraminifer stable isotope data on the complementary interval in ODP Site 1265 that supports the new correlation. Revised offsets (Tab. S12), revised composite (Tab. S13), and revised mapping pairs (Tab. S14) as well as corrected site-to-site correlation ties are given in the other supplementary materials (Tab. S15, S16, S17).

3. Paleomagnetic data Site 1263

To contribute towards the compilation of an updated Cenozoic geomagnetic polarity time scale (GPTS; see Section 4), we generated a new astronomically-tuned magnetostratigraphy at ODP Site 1263 spanning Chron C12r to C19n, as this interval was poorly calibrated elsewhere.
The geocentric axial dipole field at the geographic latitude of Site 1263, assuming that the site location did not change significantly its position within the last 40 Myr, has an inclination of ca. ±47°, which makes it feasible to reconstruct paleomagnetic polarity using only inclinations. During ODP Leg 208, the bulk of the remanence measurements was made using a pass-through cryogenic magnetometer (model 760R) (45). The Natural Remanent Magnetization (NRM) was routinely measured before and after alternating field (AF) demagnetization at 5-cm increments, with 10-cm-long headers and trailers, on all archive-half core sections from Holes 1263A, 1263B, 1263C. Time constraints permitted analysis with only 2 or 3 AF demagnetization steps at 10 and 15 mT peak values for most of the core sections. Only Section 1263B-2H3 was remagnetized up to 25 mT. The low-maximum-peak AFs ensured that the archive halves remained useful for shore-based palaeomagnetic studies.

Natural remanent magnetization (NRM) was measured on 586 discrete cube samples (dimensions 2 cm x 2 cm x 2 cm) to document magnetic polarity Chrons C12r (earliest Oligocene) to C19r at ODP Site 1263. In total, 43 discrete samples were analyzed at the Faculty of Geosciences, University of Bremen, spanning Chrons C18n to C19r, and 543 discrete samples at Istituto Nazionale di Geofisica e Vulcanologia (INGV, Rome) covering Chrons C12r to C18r.

At the Faculty of Geosciences, University of Bremen, paleomagnetic directions and magnetization intensities were determined using a cryogenic magnetometer (2G Enterprises model 755 HR). NRM was measured on each sample before being subjected to a systematic alternating field demagnetization treatment involving steps of 7.5, 10, 15, 20, 25, 30, 40, and 60 mT. Intensities of orthogonal magnetic components of the remanent magnetization were measured after each step. A detailed vector analysis (55) was applied to the results in order to determine the characteristic remanent magnetization (ChRM) without anchoring to the origin of the orthogonal projections by choosing an individual demagnetization interval for each sample. All samples but one showed a reversed, mostly steep, probably drilling induced, magnetic overprint of relative high intensity, which was easily removed at a demagnetization level of 7.5 mT (Fig. S4, S5). NRM intensities range from 3.1 to 33.4 x10⁻³ Am⁻¹ with a mean of 9.9 x 10⁻³ Am⁻¹. The maximum peak demagnetization field (60 mT) reduced the NRM to about 3% in average of the NRM intensity prior to AF demagnetization, indicating a dominant low-coercive magnetization and no clear evidence for high-coercive NRM carriers. Declinations shown here were not corrected for core orientation in the horizontal plane because our reversal stratigraphy is based on inclination data only.

The majority of the samples (> 95%) provide very stable ChRM results with maximum angular deviations (MAD), a measure of the determination of the ChRM direction, lower than 5° (mean ~3.4°). The mean normal (reversed) inclination is -32° (39°), which is slightly shallower than -47° to be expected for a geocentric axial dipole assuming that the site location had not significantly moved within the last 40 Myr.

For analysis at the INGV ODP Holes 1263A, 1263B, 1263C were sampled between August 2007 and April 2008 using standard 8 cm³ plastic cubes at the Integrated Ocean Drilling Program (IODP) Bremen Core Repository, where the core is curated. 543 samples were taken from 1263B-2H-3, 1263A-15H-7, 29, between depths of 58.52 (67.53 rmcd) and 134.78 mbsf (158.65 rmcd) and oriented with respect to vertical. To minimize sample dehydration and alteration, samples were packed in sealed bags and were stored in a refrigerated room until they were processed at the INGV. NRMs were analyzed within a Lodestar Magnetics shielded room (internal field < 200 nT) using a 2-G Enterprises automated cryogenic magnetometer (model...
755R) with an internal diameter of 4.2 cm and equipped with three DC SQUID sensors (noise level 3 x 10^{-9} \text{Am}^2/\text{kg}).

Before performing routine demagnetization of all samples a pilot study on 32 samples was conducted to determine the most appropriate demagnetization technique. Fourteen samples were subjected to AF demagnetization at successive peak fields of 5, 10, 15, 20, 25, 30, 35, 40, 50, 60, 70, 80, 90 and 100 mT. The remainder 18 samples were carefully removed from the plastic cubes and subjected to progressive thermal demagnetization from room temperature up to 650°C at the following steps: 100, 200, 300, 330, 360, 400, 500, 550, 600, 650°C.

In most cases, the pilot study at INGV demonstrated that thermal and AF demagnetization were both effective in removing secondary remanence components and in isolating the ChRM. AF demagnetization, up to peak fields of 80-100 mT, was adopted for routine treatment of samples because it was less time-consuming and because it avoided the possibility of thermal alteration during demagnetization, which would hinder future analysis of the magnetic mineralogy content. Most of the samples from ODP site 1263 are affected by a steep reversed polarity overprint which appears to be drilling induced (Fig. S6 and S7). This magnetic overprint was successfully removed at peak fields of 10-15 mT.

For a few samples, AF demagnetization above 40 mT was obscured by the simultaneous acquisition of a gyroremanent magnetization (GRM) (e.g., (56, 57) suggesting the presence of a single-domain material (Fig. S7d). The ChRM was generally isolated at fields below 40 mT and consequently the GRM acquisition did not hamper the polarity interpretation for these samples. NRM stability was assessed using vector component diagrams (58). Principal component analysis (55) was used to calculate characteristic remanent magnetization (ChRM) directions, with linear best fits calculated from a minimum of three demagnetization steps using the PuffinPlot paleomagnetic analysis application (59). The maximum angular deviation (MAD) was calculated to provide an estimate of the precision for each best-fit line. Samples were only included in this study if MAD values were less than 10°.

Five hundred twenty-nine samples (ca. 97%) are characterized by stable ChRMs which allows construction of a detailed magnetic polarity zonation for the studied interval. NRM intensities range between 2.65 \times 10^{-5} \text{A m}^{-1} and 1.55 \times 10^{-2} \text{A m}^{-1} with a mean of 5.52 \times 10^{-3} \text{A m}^{-1}. The normal and reversed polarity ChRM inclinations are grouped in two nearly antipodal clusters, as expected for reliable ChRM directions, with the mean normal and reverse inclinations of -30° and 32°, respectively. In conjunction with evidence from vector component diagrams this indicates that secondary overprints were successfully removed by stepwise AF demagnetization.

Applying calcareous nanofossil events documented in Site 1263 (45, 52; Tab. 18) to the inclination record (Tab. S19), we establish a paleomagnetic polarity interpretation (Fig. S8, Tab. S20). The resulting new Site 1263 magnetostratigraphy spanning Chron C12r to C19n is given in Table S21.

### 4. Cenozoic Magnetostratigraphy

The complete Cenozoic geomagnetic polarity time scale (GPTS) is given in the Geomagnetic Polarity Time Scale (60), the The Neogene Period (61) and The Paleogene Period (62) chapters of the Geological Time Scale 2012. Since the publication of the GPTS in 2012 several new-high resolution magnetostratigraphic records have been produced mainly refining the Paleogene Period. Here we have compiled additional recent magnetostratigraphic
interpretations from base of Chron C6n to the top of C30n (Tab. S22) and applied the new astrochronology (see below) to form a new GPTS from 19.727 to 66.393 Ma (Tab. S23) consistent with the new tuned benthic foraminifer stable isotope reference record. The differences to the GPTS 2012 in this interval are less than 400 kyr (one 405 kyr eccentricity cycle) except for Chron C21n and C22n (Fig. S9). Two independent studies have refined the early to middle Eocene magnetostratigraphy for Chron 21 to 24 using deep-sea records (52) and a pelagic/hemipelagic succession of the western Tethys Possagno section (Southern Alps, northeastern Italy;(63)). Consistently they reach similar ages and durations for Chrons C21n, C21r and C22n. In the GPTS2012, the age calibration within this interval was difficult due to relatively large uncertainty in the radioisotopic ages of the Montanari ash, located in Chron C21n and used to calibrate the GPTS (64, 65). For the interval younger than the base of Chron C6n (19.727 Ma), we applied the GPTS2012 because no major changes are apparent so far. Only the interval between top Chron C3An.1n (6.023 Ma) and top Chron C4r.1n (8.236 Ma) was replaced by the recent refinement from IODP U1337 (22), where for the first time an astronomically tuned benthic foraminifer stable isotope stratigraphy (1.5 kyr resolution) and magnetostratigraphy from a single deep-sea location was combined for this time interval.

5. Astrochronology

Dating of geological archives by astrochronology provides accurate age models at a resolution not achieved by any other dating method for the Cenozoic (66). The breakthrough of our study is to present an unprecedentedly high resolution, astronomically tuned benthic foraminifer stable isotope record spanning over the entire Cenozoic. In this section, we describe the development of the astronomically tuned age model for the deep-sea sediment successions. Quasiperiodic cycles with periods in the order of $10^4$ and $10^5$ years are found in many geological records and are known as Milankovitch cycles. The distribution and quantity of the incoming solar radiation vary due to subtle variations of the Earth’s orbit around the Sun caused by the gravitational interaction of larger bodies in the Solar System. Over the timeframe of tens- to hundreds of thousands of years, climatic patterns on the Earth respond to the quasiperiodic orbital forcing recorded as rhythmic variations in numerous paleoclimate proxy records. Milankovitch cycles show characteristic rhythms of 21 kyr (precession), 41 kyr (tilt or obliquity), 100 and 405 kyr (both eccentricity). Cyclostratigraphic age models evolve out of the recognition of these cycles in geological data using the quasi-regular Milankovitch beats as a natural metronome to measure elapsed time. Matching Milankovitch cycles containing records to long-term numerical solutions for the insolation quantities of the Earth results in highly accurate astrochronologies (66).

By combining the numerical solutions of precession, obliquity and eccentricity one can form target curves to which to correlate geological data to. Correlation of the geological data to the astronomical target results in astrochronologies that are of much higher resolution and in effect more precise and accurate than any other geological dating technique over the Cenozoic. All of the published benthic foraminifer isotope records used in CENOGRID have an astrochronology, either as provided in the respective publication or refined if needed (see Tab. S1, S24 to S32). From 0 to 20 Ma, the integrated records are tuned to an astronomical target that is an appropriate combination of eccentricity, obliquity and/or precession (20, 22, 54, 67-69). For records older than 20 Ma, only eccentricity was used as a target curve due to (a) the less evolved expression of precession and obliquity in the geological records and (b) the uncertainty in
precession and obliquity in the astronomical solutions itself. Details about the splice reference record for each record are given in Section 6 below.

The most prominent and stable astronomical cycle is the 405-kyr eccentricity cycle, which is driven by the planetary perturbations caused by Venus and Jupiter (70). Cenozoic deep-sea foraminifer stable carbon isotope records are predominantly imprinted by this cycle (71) suggesting a tight link between orbital forcing and the climate system, likely due to intricate feedback mechanisms in the carbon cycle (30, 72). Most of the orbital cycles experience marked changes in their periodicity and phasing due to the dissipative effect of the Earth-Moon system, friction, dynamic changes in the distribution of masses in the Earth and on Earths’ surface, as well as chaotic diffusion of the Solar System (14, 66, 70, 73). Therefore, numerical solutions for precession and obliquity can only provide accurate targets back to about 10 to 20 Ma (74, 75), and usable targets back to 40 Ma (70). As said before, for intervals older than 20 Ma, eccentricity-related cycles provides the only accurate tuning target.

Major components of Earths’ orbital eccentricity have a period of ~95 kyr (Mars – Jupiter), ~124 kyr (Mars – Venus), ~405 kyr (Venus – Jupiter), and ~2.4 Myr (Earth – Mars) (70). Accurate tuning to numerical solutions of eccentricity are limited by the chaotic behavior of the inner Solar System planets and the largest bodies in the asteroid belt (14, 70). Recent orbital solutions (14, 76) are valid from 0 to ~54 Ma for all eccentricity components, whereas only the 405-kyr eccentricity cycle is stable and can be used for astronomical tuning back to 200 Ma (14, 66, 77). However, comparison to geological data from the Eocene (52) and Paleocene (78) suggests that the La2010b solution (14) best matches to the observed eccentricity related cycle modulations imprinted in the records older than 50 Ma. Therefore, we used the La2010b orbital eccentricity solution to establish a consistent astrochronology for the Eocene and Paleocene. Tuning more negative carbon isotope values to short eccentricity maxima in the La2010b solution (30, 35, 79, 80) avoids distortion effects in the δ13C 405-kyr component due to the residence time of carbon in the ocean-atmosphere system and to the enhanced carbon isotope excursions of hyperthermal events (52, 81). We do not use the recently published ZB18a orbital solution because it is almost identical with the La2010b up to 58 Ma, and beyond 58 Ma it is unconstrained due to chaotic behavior (76). Furthermore, in the ZB18a solution some parameters have been varied beyond physically realistic values (pers.comm Jacques Laskar) and, thus, need to be tested first before being applied. For the same reason, we do not apply the recently proposed age (76) for the Paleocene/Eocene boundary or onset of the PETM.

All age models applied to the individual records used for the CENOGRID are given in Tab. S24 to S32. For the new benthic foraminifer stable isotope data generated from Site 1263 (middle to late Eocene) and Site 1264 (early Pliocene to late Miocene) samples we ascertained astrochronologies where necessary. Benthic carbon isotope data from the earliest Oligocene to late Eocene interval at Site 1263 exhibit a distinct eccentricity-related cyclicity (Fig. S10), which was used to tune the record from 32.7 to 42 Ma (Fig. S11). The astrochronology for Site 1264 from 0 Ma to 6.1 Ma is from Drury et al. (https://doi.pangaea.de/10.1594/PANGAEA.919489). It is based on tuning of the high-resolution %CaCO3 record was tuned to a normalized eccentricity, tilt and precession (E+T-P) target, guided by benthic δ18O where available, using a similar approach (%CaCO3 maxima/benthic δ18O minima tuned to E+T-P maxima) as in (22).
6. Cenozoic global reference benthic foraminifer carbon and oxygen isotope dataset (CENOGRID)

To compose the new high-fidelity Cenozoic benthic foraminifer stable carbon and oxygen isotope reference record, we selected the temporally best resolved deep-sea records from the Atlantic and Pacific Oceans featuring published astrochronologies. Additionally, we filled gaps, expanded these existing records, and generated new data for the early Pliocene to late Miocene (Site 1264) and middle to late Eocene (Site 1263) intervals. We included records from 14 ODP and IODP sites (Fig. S1) from the Atlantic: ODP Leg 154 Ceara Rise Sites 925, 926, 927, 928, and 929; ODP Leg 207 Demerara Rise Site 1258; ODP Leg 208 Walvis Ridge Sites 1262, 1263, 1264, and 1265; and the Pacific: ODP Leg 184 South China Sea Site 1146; ODP Leg 199 East Equatorial Pacific Site 1218; IODP Exp. 320/321 East Equatorial Pacific Sites U1337 and U1338. These sites are also ideal as it is possible to correlate between sites and compare coeval datasets, thereby highlighting the optimum, expanded intervals to use at each location in order to best target a consistent global signal. To avoid systematic interspecies isotopic offsets in isotope data (12, 82), whenever possible we only used species of the genus Cibicidoides and Nuttallides, as suggested by (4). The isotopic correction factors applied are given in Tab. S2 and Fig. S12. To obtain the best estimates of oxygen isotopic equilibrium and carbon isotopic composition of ocean deep-water dissolved CO$_2$, adjustment factors were applied (Tab. S3) and documented for each isotope value.

After compiling, generating, testing and refining astrochronologies for all the records as well as correcting interspecies offsets, we calculated a 10-point LOESS smooth and plotted the smooth along with the data (Fig. S13). Then we ascertained the optimal position to switch from one record to the next and determined the isotopic offsets between records from different ocean basins. The later step is necessary to produce a single high-fidelity reference record that documents the overall global carbon and oxygen isotope evolution in the Cenozoic. The Pacific Ocean is the largest ocean and probably best resembles a global mean, therefore all data were offset with respect to the equatorial Pacific values (Sits 1218, U1337, U1338; Fig. S14). One has to realize that single, continuous, individual high-resolution records for each of the different ocean basins and spanning the entire Cenozoic are unrealistic due to local sedimentation effects (gaps and condensed intervals) in available deep-sea sections. Comparing the evolution of ocean basin geochemistry is tempting having the new reference record at hand, but beyond the scope of this manuscript. It also involves an order of magnitude more effort to revise the published composite records from all three major ocean basins and their age models.

Ten switch points were defined where we switched from one record to the next (Fig. S15 to S24) to build a continuous high-fidelity record utilizing the specifics given in Tab. S5. We defined optimal points to switch between records to ensure the maximum resolution possible and from locations, where the isotope signals between records are highly consistent. In the latest Eocene interval the time resolution of available records is lower (Fig. S22 and S23), therefore we used the bulk isotope records to ensure that the age models are well synchronized. Due to severe dissolution across the 34.025 to 34.308 Ma interval of Site 1218, the Eocene-Oligocene Transition (EOT) (Fig. S22), we had to switch from Site 1218 to Site 1263. Low data coverage at 35.5 Ma forced us to introduce an uncertain switch (Fig. S23), which may need a refinement when additional benthic isotope records become available. However, this would require new ocean drilling campsaines, because currently no high-resolution sedimentary section provides a continuous benthic foraminifer isotope record at a single location and at the same time unaffected by dissolution.

30
After the data for the reference record were merged (Fig. S2, Tab. 33), the average sample resolution was determined. Average sample resolution from 0 to 34.025 Ma is 2 kyr and from 34.025 to 67.100 Ma is 4.4 kyr (Tab. S6). The lower sample resolution for the Eocene and Paleocene is due to lower sedimentation rates and lower sample resolution of the available records. Based on this observation, we divided the reference record in two intervals for subsequent binning and smoothing of data. We binned the data into equally spaced bins of respectively 2 kyr and 5 kyr bins for the younger and older intervals. The bin sizes were determined based on the average sample resolution. Binning was done by dividing a weighted histogram of the data by a frequency histogram of the data in IGOR Pro 8 (Wavemetrics). Where empty bins occurred, the bin was filled with interpolated data based on surrounding bins, to provide a continuous and equally spaced dataset for smoothing. To minimize the effects of outliers the records were then smoothed in IGOR Pro 8 using a nonparametric LOESS quadratic regression smooth with a tricube locally-weighted function equivalent to a 20-kyr smooth window. This equated to a 10-point smooth for the 0 to 34.025 Ma interval and 5-point smooth for the 34.025 to 67.100 Ma interval. To generate a long-term trend curve equivalent to a 1-Myr smooth window, the reference record was LOESS smoothed over 500 points for the 0 to 34.025 Ma interval and 250 points for the 34.025 to 67.100 Ma interval (Fig. S26). The binning and smoothing avoid biases due to intervals with higher sample resolution and data density and provide a balanced view for the entire Cenozoic at higher resolution than before (Fig. S27). The benthic deep-sea foraminifer carbon and oxygen isotope reference record and LOESS smoothed data are provided in Tab. S33 and S34.

**Sampling Biases** - Cenozoic deep-sea benthic foraminifer oxygen isotope data essentially track mean deep-sea temperature and ice sheet evolution (see 1, 4, 83). The temperature component of the oxygen isotope record essentially tracks mean deep-sea temperature which is set by surface conditions at sites of water mass formation. It has been suggested that the low latitudes may have contributed to sites of water mass formation under past warm climate states but the balance of evidence suggests that the main explanation for the very warm intermediate and deep waters evidenced in the oxygen isotope record during the warm climate states are warm surface water conditions at high latitude sites of water mass formation during the season of deep convection (winter) with southern hemisphere sources dominant (e.g., 84-87). Biases in benthic foraminifer records have been discussed in detail by (1, 4). Another issue is the bias due to the uneven distribution of deep-sea stable isotope data in both space and in time, particularly in the early Cenozoic with few high-resolution records. Splicing records from different regions can create artificial steps in the global record. Compared to previous records, the CENOGRID significantly reduces the temporal limitations (sampling density), but not the regional distribution issues (4). The regional distribution and water depth bias can only be solved by getting access to multiple new records from low to high latitudes over a range of water depth, a major endeavor for future scientific ocean drilling. However, the global imprint on the individual records included in CENOGRID is supported by the consistency in the variability of overlapping datasets, which partly mitigates the sampling bias caused by the regional distribution of sites. An additional bias of warmer time intervals like the Paleocene and Eocene is the perception that thermal gradients within the deep-sea were greater than today, making surface temperature reconstruction more complicated. Isotope records of planktic foraminifer to document surface ocean conditions could help here, but early diagenesis tends to bias the records towards deep-sea isotope values (see (88)).
For the Cenozoic temperature/ice-volume reconstructions the biases have limited affects. The late Neogene oceans were thermally homogeneous and a greater density of high-resolution available records means we have a greater understanding of the global versus regional imprint on individual records. In the compilation of Cramer et al. 2009, which separated records from different oceans, Eocene benthic foraminiferal $\delta^{18}$O values seem rather homogenous and suggest minor temperature differentiation amongst deep water source regions. In contrast, $\delta^{18}$O records from the Pacific Shatsky Rise Site 1209 (16) and the Atlantic Walvis Ridge Sites 1262/1263 (89) show a consistent pattern from 66 to 45 Ma. Thus, the CENOGRID presented here is assumed to be the currently best global temperature/ice-volume recorder.

For the global benthic foraminiferal carbon isotope record, spatial biases are more important toward the younger part of the record, the Neogene, because of circulation related basin to basin fractionation. Paleogene $\delta^{13}$C records from Atlantic and Pacific show the same variability but are, as expected, offset and thus can be treated as an average global carbon cycle recorder.

7. Recurrence Analysis

Recurrence analysis (RA) is used to identify transitions between different types of dynamics. A recurrence plot (RP) is a binary matrix where the coordinates of each entry mark the pair of time points with recurring states (90). A value one at column i and row j represents that state at time i recurs at time j. A recurrence is defined by the pairwise comparison of all values in the time series, whether their distance is smaller than a predefined threshold. The threshold is selected in a way that the fraction of recurrences is 10% of the number of pairwise comparisons (91). The graphical rendering of the RP can be used to get a first visual impression of the type of dynamics and to identify changes of the dynamics. RP is a powerful tool to reveal nontrivial dynamical features, i.e., not only periodic dynamics, but also intermittent regimes or chaos-chaos-transitions. For example, block-like structures in the RP identify epochs where the dynamical system is 'trapped' in a particular state.

We conducted RA on the CENOGRID in the time domain. Analysis was performed on the undetrended (Fig. S32) and detrended isotopes records (Fig. S33). Data were resampled at 0.005 Ma and detrended using a 5th order Butterworth-filter with cutoff-frequency of 0.1 Ma.

An RP contains a number of interesting and important small-scale features, such as single points or diagonal lines (15). A diagonal line corresponds to episodes of similar evolution of states. A dominance of single points indicates stochastic processes. The more diagonal lines exist with respect to single points, the more deterministic or predictable the process would be. To quantify this property, the fraction of recurrence points that form diagonal lines with respect to all recurrence points was introduced and is called "Determinism" (DET) (15). DET ranges from zero to one. If DET tends to low values, the dynamics is stochastic, whereas high values represent deterministic dynamics.

The temporal change of DET is calculated by using a sliding window approach (window size 1 Ma, moving step size 0.25 Ma). By using a specific bootstrap test, the 95% confidence level for significantly elevated DET values can be determined (92). It is important to note that each given DET value corresponds to the center of the moving window. Therefore, the analysis provides insight to significant changes in DET, equal to significant changes in the dynamics of the system, that occur within less than 1 Ma. The method cannot resolve abrupt changes on the order of thousands and tens of thousands of years. Nevertheless, the analysis of the detrended data (Fig. S33) documents distinct white bands in the recurrence plots. These bands mark
transitions in the climate dynamics and coincide with major changes or events recorded in benthic foraminifer isotopes.

8. Global Temperature Record and Past Atmospheric CO$_2$ Levels

We use the approach in (93) to transpose the deep-sea temperature changes recorded in the benthic foraminifer oxygen isotope data into average global changes in surface air temperature scaled to the 1961–1990 mean. Deep-sea benthic foraminifer oxygen isotope $\delta^{18}$O values are controlled by changes in deep-ocean temperature and global ice mass over the Cenozoic (83). Therefore, variations in ice growth need to be taken into account prior to estimating deep-ocean temperature changes. Prior to the onset of large polar ice sheets on Antarctica at 34.025 Ma, deep-sea temperature can be approximated assuming that most of the $\sim$1.8‰ increase in $\delta^{18}$O from the Early Eocene Climate Optimum (EECO) to the end of the Eocene is due to a 7–8°C change in temperature (1). After the major onset of a large polar ice sheet in Antarctica at the Eocene-Oligocene Transition (EOT) ice volume and deep-sea temperature changes both contribute to the variance in benthic foraminifer $\delta^{18}$O values (94). With the appearance of larger ice sheets in the Northern Hemisphere the contribution of global ice mass variations to $\delta^{18}$O values increased at 3.6 Ma and 1.81 Ma. Taking this into account, (93) proposed three equations (equations 1 to 3 in Tab. S7) to transfer deep-sea $\delta^{18}$O values into temperature estimates for the Cenozoic. We applied these three equations to the three time intervals to compensate for different contributions of ice sheet variations to the $\delta^{18}$O signal. Our intent is not to develop a new scheme to transpose the benthic foraminifer record but just to account for the potential influences of ice-volume during those periods for which major ice-sheet expansion occurred (on Antarctica in the Miocene and the N. Hemisphere at 2.7 Ma) as indicated by independent evidence.

To compare changes in global temperature relative to today, the deep-sea $\delta^{18}$O-derived temperatures have to be transposed into surface air temperature changes. We follow the relation between deep ocean and surface temperature change (equations 4, 5, 6 in Tab. S7) and calculate the temperature change with respect to the Holocene mean temperature of 14.15 °C as given in (93).

Estimates for past atmospheric CO$_2$ levels are compiled from (95) and references therein, (96) and references therein, and from (97-105). Atmospheric CO$_2$ estimates including the upper and lower estimate were LOESS smoothed in IGOR Pro 8 over 30 data points. References in (95) are on the GPTS2012 (60). Additional atmospheric CO$_2$ estimates are on their individual age models, because the uncertainty for atmospheric CO$_2$ estimates is much larger than the difference between GPTS2012 and our updated GPTS ages.
Supplementary Text
S1 - Earth’s Trends, Rhythms, and Aberrations

**Trends**: The general long-term trends in global climate as represented by the spliced oxygen isotope record (the red curve in Fig. 1) confirm the patterns obtained in the previously published low-resolution stacks (e.g. (I)). These trends are partly influenced by modifications in boundary conditions due to tectonic processes (106) including continental geography and topography, oceanic gateway locations and bathymetry, but mainly by the concentrations of atmospheric greenhouse gases, finely balanced between volcanic CO$_2$ outgassing and consumption by weathering of silicate mineral rocks (107). It is generally accepted that the overall increase in the relative abundance of oxygen isotopes values reflects the formation of large polar ice sheets and a decrease in mean deep-ocean temperature, a trend that largely corresponds with a long-term decline in atmospheric pCO$_2$. Supported by more recent independent evidence, its well accepted that the prominent steps towards greater oxygen isotope values mark major stages of polar ice sheet growth: the Eocene/Oligocene Transition (EOT) 34 million years ago with the large scale expansion of the East Antarctic Ice Sheet (EAIS, 17), the middle Miocene Climate Transition (mMCT, 108) 13.9 million years ago with the expansion of the West Antarctic Ice Sheet (WAIS) and with the re-expansion or further expansion of the EAIS, and the intensification of the Northern Hemisphere Glaciation ~2.7 million years ago (109).

The benthic carbon isotope record, which is generally assumed to be sensitive to changes in the global carbon cycle (110), over long time scales, shows a number of key features, most of which often relate to climate (Fig. 1). Aside from the effects of the K/Pg extinctions (111), the most striking features of the marine C isotope record are the late Paleocene carbon isotope maximum (PCIM) and the Miocene Monterey Event, thought to represent periods of large changes in organic carbon burial caused by enhanced marine productivity or increased burial of biomass, terrestrial and/or marine (20, 82, 112-114). Synchronous with the first major glacial event in the Pliocene at 3.3 Ma (M2), the amplitude in both the carbon and oxygen isotope signal increase on time scales of $10^5$ years.

**Rhythms**: The main contribution of the current study is to reveal the general patterns of rhythmic fluctuations as superposed on the long-term trends. Fluctuations on time scales of $10^4$ to $10^5$ years dominate early-mid Cenozoic global oxygen and carbon isotope records (the blue curve in Fig. 1) and are related to the short eccentricity oscillations of about 95,000, 124,000 and 405,000 years, more distinctive in the carbon isotope record (Fig. 3). The influence of eccentricity on insolation are small compared to those of obliquity and precession, but it is the only orbital parameter that controls the total amount of solar radiation received by the Earth averaged over the course of one year (14). More importantly, eccentricity modulates the amplitude of the precession cycle affecting the intensity of seasons (e.g., during maxima in eccentricity, more intense wet and dry seasons caused a decrease in the net burial of carbon) (30). Modeling suggests that low- and mid- latitude processes in the climate system respond in a nonlinear way to insolation forcing (28, 31-33). Important feedback to be considered involves the global monsoon which plays a key role in distributing moisture and energy as driven by low-latitude insolation (31, 32). The high-resolution isotope record thus documents a nearly 50-million-year sustained dominance of low-latitude processes on Earth’s climate system.

After the mMCT at 13.9 Ma, Earth’s climatic regime and dynamic response changed with the re-expansion of Antarctic ice sheets and possible initiation of Northern Hemisphere Ice
Sheets (NHIS) in the late Miocene (110). After that time, a persistent response to obliquity gains power in the oxygen isotope signal, further strengthening after 7.7 Ma (Fig. 3; 22, 36), documenting the increasing influence of high latitudes on global climate variability caused by the expansion of polar ice-sheets. In contrast, carbon cycle dynamics remain strongly paced by eccentricity after the mMCT (36, 67), but obliquity only noticeably imprints on carbon isotope variability after 7.7 Ma before becoming the dominant influence in both oxygen and carbon isotopes after 6.4 Ma (11, 22, 114) (Fig. 3). About 800,000 years ago, the amplitude in oxygen isotope data, now showing a characteristic asymmetric pattern, increased due to the waxing and waning of large Northern Hemisphere ice sheets. The origin of the prevailing quasi 100-kyr cycle of the ice age is still an unsolved problem, but it is likely not directly related to the 95-kyr and 124-kyr eccentricity cycle. However, from the perspective of the last 66 Myr, the past 800,000 years represent a very unusual time with its asymmetric large scale amplitude fluctuations in oxygen isotope values due to the waxing and waning of massive bipolar ice-sheets.

**Aberrations:** Aberrations from the background global trends and rhythms are the third important feature of the Cenozoic deep-sea benthic carbon and oxygen isotope record. Transient climate warming events lasting 40-kyr to 200-kyr occurred frequently in the late Paleocene and early Eocene. Known as hyperthermal events, they are characteristically coupled to negative excursions in carbon and oxygen isotope values, which document rapid warming of the climate system on geological time scales associated with large perturbations of the carbon cycle (4, 16, 39, 115). By far the largest event, unprecedented in the last 100 million years, was the 5 to 8°C global warming of the Paleocene/Eocene Thermal Maximum (PETM) at ~56 Ma. It is evident that hyperthermals are orbitally forced disruptions in the carbon cycle (39, 115, 116) with infrequent and variable additional carbon released from slowly recharging reservoirs (117). These transient global warming events are an intrinsic feature of the climate system in the “hothouse mode” as is apparent in the early Eocene. After the East Antarctic Ice Sheet expansion at the EOT at ~34 Ma ago, only the Tortonian Thermal Maximum at 10.75 Ma (36) stands out as a potential similar warming event, but its global nature needs to be validated by additional records. High-amplitude variability of δ¹⁸O and δ¹³C during the Miocene Climate Optimum is reminiscent of hyperthermals (δ¹⁸O and δ¹³C decreases coupled to intense transient carbonate dissolution events). If we assume that pCO₂ level reconstructions around 600 ppm for that time are correct, the climatic implications are major. The detailed isotope record of the Cenozoic encompasses many more anomalies, but of lower magnitude than those discussed above. Many of these were very likely orbitally controlled dynamics in the climate system enhanced by non-linear effects (30).

**S2 - Milankovitch cycles and astronomical tuning**

Periodic variations in Earth’s orbit around the Sun have remained relatively uniform over hundreds of millions of years. However, the climatic response to resulting changes in insolation have varied considerably (1, 69, 106). Average global temperature over millions of years mostly varied in concert with the concentration of greenhouse gases such as atmospheric CO₂ (118). Superposed on the long-term trends, fluctuations omnipresent in deep-sea benthic foraminifer isotope data are driven by variations in Earth’s orbital parameters (119) with periodicities corresponding to the so-called Milankovitch cycles of precession (19 and 23 kyr), obliquity (41 kyr) and eccentricity (100 and 405 kyr). These cycles are the key quasi-periodic climate influencing changes in Earth’s orbital geometry caused by the gravitational interaction of larger
bodies in the Solar System (69). Although the expression of these cycles in sediments can change with time the heartbeat of climate, the Milankovitch cycles, can be used as a metronome telling time. Such astronomical tuning, the correlation of Milankovitch cycles in sediment archives to numerical computations of insolation is now a cornerstone calibrating the geological time scale (66), and central to the contribution of this study.

S3 - Sampling resolution and site location artefacts

We have addressed the sampling biases of the CENOGRID already above. Here we elaborate on the limits and possible artefacts arising from the selection of ocean drilling sites. Sedimentary records are a mix of local, regional and global signals and their interactions. Deep-sea and far offshore ocean drilling records are good records to investigate global changes, as proven in 50 years of scientific ocean drilling. However, on time scales of ten thousand to one million years specific locations are better suited for resolving the higher frequency components of climate variability, in part, because of proximity to certain climate system processes (circulation/weathering). Just as an example, the Ceara Rise (ODP Leg 154) sites with relatively high sedimentation rates for a pelagic region and a location in the western Equatorial Atlantic (i.e., relative to the boundary between Antarctic Bottom Water and Northern Component Water) should record both obliquity and precession. Oligocene-early Miocene records from the eastern South Atlantic Walvis Ridge might not be as sensitive to obliquity (for discussion see (120)).

How much of the signal in the Oligocene-early Miocene Site 1264 δ18O or δ13C is local versus global is debatable and can only be assessed with high fidelity records from multiple other sites from different regions and water depths (e.g. (121)). Stratigraphically continuous and splices composite scientific ocean drill cores are still rare. It will take another 50 years of scientific ocean drilling to systematically retrieve suitable records and generate high-resolution benthic stable isotope records needed to clearly disentangle regional from global signals as well as regional from global responses to astronomical forcing.

Due to the limited selection of currently available cores the results in our study will be biased towards the particular record used from Atlantic or Pacific. We are confident that the selected records still for the most part mainly reflect a global signal due to their well-connected/ventilated positions within vast ocean regions and high resolution expression of variability mirrored in other records. For the records in CENOGRID, we chose to apply a minimal tuning approach to avoid introduction of precession or obliquity components into the records prior to spectral analysis. The selection of mid- to low-latitude sites could bias the records as well as their position in the water column and thus the origin of the signal recorded. Benthic δ18O values mainly tell about the climate (temperature) in the areas of deep-water formation (e.g., the high latitudes) and change in seawater isotope composition by ice sheet variations. Benthic δ13C values are more complex, they mostly reflect the dissolved inorganic carbon inventory of the ocean and are influenced by the ocean circulation patterns. Records will thus be biased depending on their geographic position and influence the outcome of the spectral analysis. Thus artefacts can arise from changing between records. Additionally, the sample resolution (Fig. 28) and sedimentation rate at a given location will bias the outcome. Slow sedimentation rates of much less than 1 cm/kyr tend to amalgamate precession and obliquity related cycles, enhance the amplitude of longer cycles like eccentricity, and potentially lead to cycle misidentification. We use the best resolved records in the CENOGRID to avoid aliased signals or amplitude enhancement.
Different approaches for time series analysis to produce evolutive spectrograms exist. We applied various methods to avoid misinterpretation by method based artefacts. The Evolutive Power Spectral Analysis (Fig. S29) and the evolutionary FFT spectrogram (Fig. 3) give similar results but tend to smear out at significant power intervals. Wavelets generally perform better in identifying brief intervals with significant cyclicity, because this time series analysis tool adjusts window size for each periodicity. We computed 3D wavelets on CENOGRID (Fig. 29), which show a bit more detailed but consistent pattern compared to the Evolutive Power Spectral Analysis and evolutionary FFT spectrogram. The enhanced persistent appearance of obliquity cycles at around 13.9 Ma in $\delta^{18}$O and 7.7 Ma in $\delta^{13}$C can be seen in the 3D wavelets as well. These analyses are consistent with findings at multiple locations in different oceanic basins that pervasive obliquity pacing is imprinted in benthic oxygen and carbon isotopic records since the late Miocene to early Pliocene. A similar picture evolved using the Thomson multi-taper method (MTM, (122), Fig. S31). The latter method reveals in $\delta^{18}$O data some more power in the obliquity band around 14.5 Ma, 19.5 Ma, 21 Ma, 23.7 Ma, 30.5 Ma, and 43 Ma. All of these intervals are characterized by low eccentricity modulation of the precession and larger obliquity amplitudes in the astronomical forcing. Higher power intervals in the obliquity band at 56 Ma (Paleocene/Eocene Thermal Maximum) and the Early Eocene Climate Optimum (EECO, 49.14 to 53.26 Ma) are an artifact of the hyperthermal events (16). The weak response to obliquity in the early Cenozoic could be partly biased by the selection of sites. Enhanced obliquity cyclicity was reported during the Oligocene from the Pacific ODP Site 1218 (35) in benthic stable isotope data, the early Miocene and Oligocene from Southern Ocean ODP Site 1090 (123) and Atlantic Ceara Rise ODP Leg 154 sites (124-128) in magnetic susceptibility and benthic stable isotope data. In our study we have revised the astronomical tuning for ODP Site 1218 using a minimal tuning approach. Spectral analysis of the benthic data on the new age model reveals less obliquity contribution than previously thought. Higher resolved benthic records spanning the early Miocene and late Oligocene from ODP Site 1264 (Walvis Ridge, (120)) and ODP Site U1334 (121) show less imprint of obliquity related cyclicity then the previous lower resolution record. We point out here that more detailed records spanning all intervals of the Cenozoic Era are needed to properly resolve the detailed response to astronomical forcing. Low amplitude variability will make this a challenging task for most of the Cenozoic, but we strongly recommend here to generate records at high resolution (2-3 kyr) and on monospecific species to avoid aliasing and distortion of the primary isotope signal.

S4 - Evolution of Earth’s global temperature and its coupling to atmospheric CO$_2$ changes

Since the industrial revolution in the 1850s atmospheric CO$_2$ concentrations have risen as a result of anthropogenic carbon (C) emission due to fossil-fuel burning and net land use (129). At present, concentrations have increased to 415 ppm or by 40% relative to pre-industrial times, and depending on future fossil fuel (FF) consumption will rise following one of several potential C trajectories, or Representative Concentration Pathways (RCP). The response of future climate to anthropogenic carbon release, however, still has a large degree of uncertainty due to the nonlinear behavior of feedbacks in climate models, for example clouds. This is particularly true for scenarios of CO$_2$ levels exceeding those of the last several million years (~400 ppm) which are closer to the early Eocene levels (>800 ppm). Although reconstructions of deep time climate states and their associated dynamics, cannot be used as direct analogs for future climate due to different climate boundary conditions (e.g., configuration of continents and mountain ranges,
etc.), they can be used to assess climate model sensitivity, and thus test hypotheses about feedback mechanisms.

After removing the contribution of large polar ice-sheets, deep-sea benthic foraminifer oxygen isotope data essentially track mean deep-sea temperature over the Cenozoic (1) which can be transferred into average global changes in surface air temperature by scaling to the 1961–1990 average (Fig. S34; (92)). Over the same period atmospheric CO\(_2\) levels can be reconstructed by a variety of methods (130). Assuming that atmospheric CO\(_2\) concentrations mainly pace Cenozoic climate (131-133) a comparison of the RCP results to the average global temperature changes derived from the high-resolution benthic foraminifer record helps to (A) identify periods in Earth’s history that are comparable to future scenarios and (B) unravel how dynamic climate evolves in these modes.

At 415 ppm, present day CO\(_2\) levels are similar to those of the middle Pliocene (Fig. S34; (134)), before the establishment of a large Northern Hemisphere ice sheet (NHIS). By the year 2100 atmospheric CO\(_2\) could reach 935 ppm, possibly causing a global warming of more than 4\(^\circ\) Celsius according to RCP 8.5 (Fig. 31, (44)). The Miocene Climate Optimum, more than 15 million years ago, is the most recent period in the Earth’s past with similar temperature increase relative to preindustrial (1961-1990), a time with insignificant NHIS and dynamic Antarctic Ice Sheets (e.g. (135-138)). If there is no considerable decrease in carbon emissions by the year 2200, atmospheric CO\(_2\) could reach almost 2000 ppm, likely causing a warming of more than 8\(^\circ\)C by the year 2300 (44, 139). The Earth was as warm during the middle to late Eocene (>40 Ma) and mid-Paleocene (~60 Ma) (Fig.31, (44)), a time of no significant polar ice-sheets and CO\(_2\) level much higher than today (133). During the EOT, 34 Ma ago, the massive expansion of the Antarctic ice sheet is thought to be related to a CO\(_2\) threshold for the establishment of continental ice sheets (~600 ppm; (140-142)). Even under the caution that past climates may not be direct analogues to Earth’s short term future, because of non-linearities in forcing and feedbacks of the climate system (143, 144), under further unmitigated emissions of CO\(_2\) there is a risk of pushing the climate system towards a state with ephemeral glaciations at the poles, where the climate system will lose a key thermostat and the influence of low-latitude processes on global climate will be strengthened. As is apparent in long-term detailed reconstructions such a major shift between states in climate would be unique in the past 66 Mya. While there have been similar magnitude warming events (e.g., the PETM), the main difference is that during these past events, the planet was already warm and ice-free, so lacking a major amplifying feedback on the climate system. Moreover, despite state, carbon cycle feedbacks have operated to varying degrees. As such, it is very likely that the rate and impacts of future warming will be severe and exceedingly challenging to forecast.

Overview of characteristic remanent magnetization results and data versus depth at Site 1263. Maximum angular deviation (MAD), declination and inclination results of discrete samples as well as the final magnetostratigraphic interpretation applying calcareous nannofossil datums.
Fig. S9.
Comparison of magnetochron boundary ages between GPTS2012 (60) and astronomically tuned ages compiled from ocean drilling sediment cores (this study).
Spectral analysis of middle to late Eocene benthic foraminifer carbon isotope data plotted versus depth at Site 1263. Based on the calcareous nannofossil biostratigraphy and the magnetostratigraphy, sedimentation rates can be estimated showing that the dominant cycles with frequency of 0.2 cycles/meter (5 m-long cycles) are related to the 405 kyr eccentricity cycle. Shorter cycles in the order of 0.8 cycles/meter (1.25 m-long cycles) are related to short eccentricity.
Fig. S11. – oversized figure
Astronomical tuning of bulk and benthic foraminifer carbon isotope data from Sites 1258, 1262, 1263 and 1265 spanning the Paleocene and Eocene. For orientation, inclination data with magnetostratigraphic interpretation and calcareous nannofossil event datums are plotted along all available bulk and benthic carbon isotope data versus depth. The published age model for Sites 1262 (Tab. S28) and 1263 (Tab. S29) have been extended in this study from 32.7 to 41.9 Ma at Site 1263 to develop a complete astrochronology for the Paleocene and Eocene. Outstanding events (transitions, hyperthermals, boundaries) are indicated. Target for astronomical tuning was the numerical solution La2010b for eccentricity from (14). In the top panel the La2010b solution is plotted with the detrended carbon isotope data to document the good agreement between data and model with respect to the amplitude modulation of short eccentricity.
Fig. S12.

Paired isotope analysis of benthic foraminifers *N. truempyi*, *O. umbonatus*, and *C. praemundulus* for (left) $\delta^{18}$O and (right) $\delta^{13}$C. Paleocene, gray; Eocene, black; Eocene this study in dark red. The light red linear regression line for $\delta^{18}$O and $\delta^{13}$C paired analysis of *N. truempyi*, and *O. umbonatus* (16) include data from (16, 145-147) to establish the isotopic adjustment (i.e., correction) factor for benthic foraminifers from Site 1209. The 1263 data from our study of the late Eocene fall on the established regression line from Site 1209. $\delta^{18}$O and $\delta^{13}$C paired analysis of *N. truempyi* and *C. praemundulus* provide a regression line to adjust between the species. See Tab. S2 for details on correction factors used in this study.

Benthic foraminifer stable oxygen isotope compilations from (8) and (1) as well as the Megasplice of (5) and the recent composite of (10) compared to the new composite Cenozoic reference global benthic carbon and oxygen isotope dataset (CENGRID). Note the low resolution in the Paleocene and Eocene for the previous compilations.
Fig. S28.
Average sample resolution over one million year intervals for the CENOGRID benthic stable isotope data.
Evolutionary Power Spectral Analysis (EPSA) on the short-term LOESS smooth of the astronomically-tuned CENOGRID using ASTROCHRON (148). The EPSA documents, as in Fig. 2, the dominance of the 405 kyr and ~100 kyr eccentricity cycles from 67 to 13.9 Ma. After 13.9 Ma enhanced obliquity related cyclicity appears first in the oxygen isotope record. In the carbon isotope data obliquity becomes more dominant around 7.7 million years ago. Isotope data have been detrended by the long-term LOESS smooth trend and evenly samples every 2 kyr. The following code was used to compute the spectra in ASTROCHRON:

eha(dat,tbw=2,65536,0,80,0.02,5,demean=T,detrend=T,siglevel=0.90,sigID=F,ydir=1,output=0,pl=2,palette=3,centerZero=T,ncolors=100,"Frequency","Location",genplot=4,verbose=T).

Fig. S29.
Fig. S30.

3D wavelets of the CENOGRID. Wavelet analysis of the Cenogrid δ¹⁸O (top panel) and δ¹³C (bottom panel), using a Morlet transform (149,150). Prior to wavelet analysis the records were resampled at 2.5 kyr resolution, detrended using a Notch filter (frequency = 0.0 Myr⁻¹, bandwidth = 1.0 Myr⁻¹) (151), and normalized using a 1-Myr sliding window. Gray lines indicate the 95% significance contours. Shaded areas indicate the cone of influence.
Fig. S31.
Evolutive spectra of CENOGRID computed using the Thomson Multi-taper method (122), with v.0.0.7 Spectrogram tool (https://paloz.marum.de/confluence/display/ESPUBLIC/Spectrogram). Data were interpolated to even time steps, and then computed with 700kyr windows stepped every 70kyr. MTM settings were bandwidth product: 3, number of tapers: 4. For the isotope data, the amplitudes are displayed on a logarithmic scale.
Fig. S32.
Recurrence Plot of undetrended benthic foraminifer carbon (left) and oxygen (right) isotope data versus age; important transitions and events given.
Fig. S33.
Recurrence Plot of detrended benthic foraminifer carbon (left) and oxygen (right) isotope data versus age; important transitions and events given. Note: transparent areas mark transition zones and events.
Fig. S34.
Past and future trends in global mean temperature and atmospheric CO$_2$. Deep-sea benthic foraminifer oxygen isotope values spanning the last 67 million years are a measure of global temperature and ice volume. Here the record was first converted to a deep-sea temperature and then projected to surface air temperature change (92). Temperature is relative to the 1961–1990 global mean, and plotted along with estimates for past atmospheric CO$_2$ levels (see Section 6. and supplementary Text S1). Temperature and CO$_2$ data from ice core records of the last 25,000 years illustrate the transition from the last glacial to the current warmer period, the Holocene.

Historic data from 1850 to today ((152, 153); 415 ppm www.esrl.noaa.gov/gmd/ccgg/trends) show the distinct increase for both constituents after 1950 marking the onset of the Anthropocene (154). Future projections for global temperature (44) and CO$_2$ (139) for three Representative Concentration Pathways (RCP) scenarios in relation to the benthic deep-sea record suggest that by 2100 the climate state will be comparable to the Miocene Climate Optimum (~16 million years ago), way beyond the threshold for nucleating continental ice sheets (140). If emissions are constant after 2100 and are not stabilized before 2250, global climate by 2300 might enter the hothouse world of the early Eocene (~50 million years ago) with its multiple global warming events and no large ice sheets at the poles.
Fig. S35.

Scatter plots of deep-sea benthic high-resolution (A) and long-term (B) carbon versus oxygen isotope data variations as well as long-term atmospheric CO$_2$ concentrations versus benthic carbon (C) and oxygen (D) isotope data. The relation to atmospheric CO$_2$ concentrations for both carbon and oxygen, as representative for the global carbon cycle and temperature trends, suggests that the present climate system as of today 415 ppm CO$_2$ is comparable to the Coolhouse in the Miocene, but will move abruptly into the Warmhouse or even Hothouse by 2100 if emissions of CO$_2$ are not diminished.
